Evaluating Cross-chain Settlement and Exchange in Cryptocurrency

Name	Carl-Johan Andersson
CAS	caan0156@umu.se
CS	c14can@cs.umu.se
Date	2019-05-27

Abstract

While Bitcoin is beginning to cement it's core protocol and principles, the related technologies around it, such as atomic swaps and lightning network could still be considered to be in an infant state when it comes to understanding and development. Here you will find atomic swaps being evaluated in depth, both off-chain and on-chain. In this thesis you will find reasoned and somewhat well defined standards and protocols on how atomic swaps should be performed in the future, which was the goal.

Oskar Janson (oskar.janson@cinnober.com)

Glossary

Cryptocurrency - A currency backed not by centralized authorities but by mathematical evidence and clever mechanisms.

Bitcoin - The very first and most mature cryptocurrency on earth, 1 bitcoin = 1฿.

Litecoin - A alternative to Bitcoin, mostly a clone with a few changes.

satoshi - The smallest fraction of a bitcoin. 100.000.000 satoshis = 1฿.

Satoshi Nakamoto - The pseudonym used by the creator of bitcoin.

Proof-of-work - A system where someone can prove mathematically that work was put into doing something.

Hash - A hash is a mathematical way of producing a one-way "fingerprint" of any data, easy to check but nearly impossible to reverse.

Nonce - A temporary value, most often a number. Used to give the hash of a data structure a unique outcome. The value fills no purpose other than altering the hash.

Mining - In the context of cryptocurrency refers to looking for a valid hash in a proof-of-work system. Most often by putting random numbers in the nonce field until a valid hash is found.

On-chain - Something that is on-chain (for example a transaction) has been included in the blockchain and can be safely assumed to be immutable, in other words can not be changed.

Off-chain - Something that is not on the blockchain. Often meaning that it can be altered in some way.

Atomic (Adjective) - Something that only has two outcomes. Either completed fully or no changes to the state at all. An atomic task can not be half completed.

Alice and Bob - Alice and Bob are two fictional people used in examples. Sometimes referred to as just A and B

Pre-image - A pre-image is the name given to data as it was before being altered. For example $\text{Hash}(D) = H$, in this case D would be the pre-image of H.

Merkle tree and merkle root - A merkle tree is a tree structure created from hashes of a list of elements. The root is the singular node formed at the top of the tree. The tree makes it easier to check if an element was part of the original list without

Payment channel specific glossary

Node - A participant in a payment channel or lightning network. Sometimes goes under names such as peer, agent, actor or participant.

Channel - A construct where two participants can exchange transactions outside of the blockchain. The medium of exchange can be assumed to be over an internet connection, but could technically be over almost any medium.

Lightning network - A lightning network is a network of connected payment channels. Where payments can be routed across multiple nodes and channels safely.

HTLC - Hashed time-locked contract, a contract defining the outcomes of a payment over multiple channels.

Chapter 1

Introduction

Although blockchain and other types of distributed ledgers are still in their infancy, a growing number of people and companies are starting to see that they hold great promise, especially when it comes to financial technology, where things like trust and security is held to be very important.

1.1 The origins of Bitcoin

The most well known, developed and researched blockchain technology is Bitcoin. The mysterious nature of Bitcoins creator makes it hard to pinpoint how and when the idea was first thought up or when the development actually started. The most exact way would be to pinpoint at: 2009-01-03 18:15:05[9], which is the timestamp in the very first block in the Bitcoin blockchain, however the white paper (**Bitcoin: A Peer-to-Peer Electronic Cash System**)[23] specifying the technical details circulated on cryptographic mailing lists as early as 31 October 2008, and the domain name `bitcoin.org` was registered 18 August 2008.[17]

1.1.1 Satoshi Nakamoto

The author name given in the white paper is **Satoshi Nakamoto** (Often referred to by a single name, like Nakamoto or Satoshi¹), this name is believed to be a pseudonym. Nakamoto remained in the bitcoin community for a couple of years, regularly posting on the forum `bitcointalk.org` and keeping up with conversations in the mailing list. Those who have been interested in finding out Nakamoto's real identity have analyzed his active time and language used. The findings were that Nakamoto was most active during Western European day time, and he also used a lot of Anglo-colloquialisms such as "bloody hard" [13], and "flat" instead of apartment, so a popular theory is that Satoshi lived in Britain at least during this time.[17]

April 23, 2011 was the last time anyone ever heard from Satoshi Nakamoto, in a mail to a fellow developer Mike Hearn he said "I've moved on to other things. It's in good hands with Gavin and everyone.".[15] Speculations on who Satoshi really is are still going strong even to this day, but Nakamoto's true identity is so far unknown.[17][18]

¹Not to be confused with the tiniest fraction of a bitcoin, which is always written with a small letter: `satoshi`. See glossary

1.2 Basics on Bitcoin

Most people, even the layman with no blockchain experience, have at least heard of Bitcoin. But the exact details of how it works is not common knowledge. Described in a single sentence: Bitcoin is a currency where a communal ledger, that is shared between all participants in the whole world, dictates who owns what in terms of money or other assets. The regular monetary system we are used to has a centralized authority, for example a central bank, who decides how much money is in circulation, who can transact with who etc. The monetary system presented by Bitcoin has no centralized authority, instead it relies on decentralized, trust-less verification.

These usually are the main concerns people have with distributed ledgers:

- How is spending someone else's money prevented?
- What prevents someone from "printing" more Bitcoins?
- How is spending the same money in different places in the world prevented?
- How is the consensus on the order of transactions reached?
- How do I interact with it?
- What type of transactions can you make?

These questions will be given answers in the sections below.

1.2.1 Digital signatures

Bitcoin would not be possible at all without the underlying cryptographic mathematics. When it comes to proving ownership in Bitcoin ECDSA (Elliptic curve digital signature algorithm)[24] is used. Elliptic curve cryptography will not be covered in depth here but the basic idea is that you have a private and public key. The public key can be shared with anyone without danger, the public key can be derived from the private key, but not the other way around, this is something called trap-door mathematics.[24][16] This means that it is easy to go one way via equations. But going back is nearly impossible.

The reason for it not being completely impossible is because any potential attacker could always just keep guessing private keys until the right one is found. However with a sufficiently large private key, let's say 256-bits, and a computer that could check one billion billion (10^{18}) private keys every second (If such a machine could exist at all) it would still take $\frac{(2^{256}/10^{18})}{(60 \cdot 60 \cdot 24 \cdot 365)} \approx 3.67 \cdot 10^{51}$ years to check all possible private keys.

The most common transaction made on the blockchain is one where you "pay to" a public key. Who ever holds the private key paired with that public key can then via a mathematical equation prove that they hold the private key without actually revealing the private key.[14]

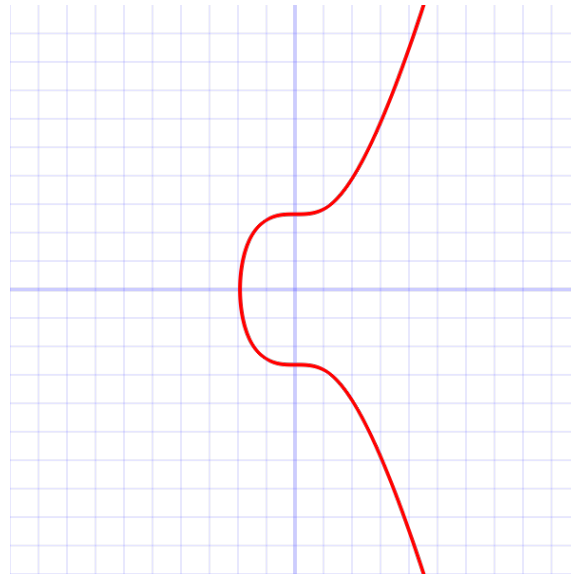

Figure 1.1: The Secp256k1 plotted over real numbers. Note that the real curve is over a field, and thus looks more like a scattering of random points

The elliptic curve used can hold different parameters that defines it, certain elliptic curves are standardized and have their own names. The curve used in Bitcoin is named Secp256k1.[25][16]

The typical curve used in Elliptic curve cryptography is on the form $y^2 = x^3 + ax + b$. The Secp256k1 is defined with $a = 0$ and $b = 7$, making the full Secp256k1 equation: $y^2 = x^3 + 7$. Which is plotted in figure 1.1. For more in depth on elliptic curve cryptography see section 2.2

1.2.2 Blocks and the blockchain

A block is fairly simple to understand, it is simply a datatype or structure that holds information about itself, all the transactions that can fit and the previous block in the chain (more on that in a bit). Because every block holds information about the previous block you can follow all blocks backwards in time all the way back to the original, also called the genesis block.[9] This is what is referred to as the blockchain.

A block could be added to the chain by anyone in the world. However it will only be accepted if it has sufficient proof-of-work, and this is the key to how consensus is reached in the network.[16]

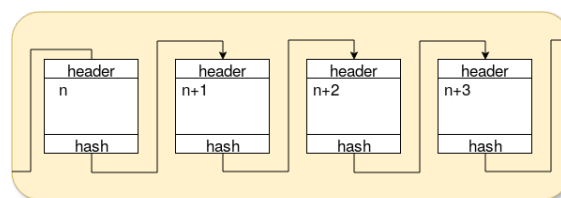

Figure 1.2: A basic overview of a blockchain

Block-header

Each block has a section of data called a header. The header contains meta-data about the block itself such as the version number, the id of the previous block in the chain, a

timestamp of when the block was mined, the merkle root² of all transactions (serves as proof of what transactions was included in the block) and a 32-bit field called nonce.

The size of the header is always 80-bytes, a blocks id³ is equal to the hash of its header. For example the genesis block in the Bitcoin blockchain has the id:

```
000000000019d6689c085ae165831e934ff763ae46a2a6c172b3f1b60a8ce26f
```

Something that you will find with all block-ids is that they always have leading zeroes. This is a side-effect caused by mining and proof-of-work as explained in section 1.2.3.

1.2.3 Proof-of-work

Proof-of-work is, just like digital signatures, based in cryptographic mathematics. Before we go on, you first need to understand what a hashing algorithm does, the hashing algorithm used in Bitcoin is called **SHA256**. **SHA256** takes in data of any size and produces a sort of finger print of 256 bits.

For example the **SHA256** of the text "cool":

```
echo "cool" | openssl sha256
```

Produces:

```
27c16ce7e3861da034af1bb356d6a4f38cb84fa65d51fa62f69727143b4c6b60
```

The text produced is actually bytes represented in a hexadecimal number system, in fact the entire string can be considered to be a very large number. Just like with the digital signature there is no known viable way that can take a hash and find what the original data that produced it was.

There is a term in Bitcoin called mining difficulty, or just difficulty. This is a large number, 256 bits to be exact. When you want to add a new block to the chain you have to do something called mining, this is a process where you change the nonce-bits in the block-header until the hash of the blockheader (Think of this as a number) is less than the target difficulty. The term hashpower refers to how many times the machine you are using to mine blocks can test a certain combination of variables per second, or H/s (Hashes per second).

The difficulty of mining a block is adjusted about every 2 weeks (every 2016th block to be exact). The difficulty is calculated by each individual node whenever the block count is a multiple of 2016, the nodes go by the timestamps in the blocks, and should thus all reach the same conclusion. The new calculated difficulty is the one all the next 2016 blocks have to reach.^[16]

The accepted order of transactions is the order going backwards from the latest block on the longest chain. The longest chain is always the one that the majority is mining towards. What it basically means is that as long as you trust 51% of the participants in the network you can also trust that the order of transactions is correct.⁴ This mechanism prevents things like double spending the same money and holds a property called emergent consensus, which means that eventually the entire network will agree on the order of transactions.

In figure 1.3 is a diagram showing the longest chain, meaning the chain with most proof of work. The block in green is the latest block on that chain. The yellow block is what is

²See glossary

³Block id and block hash refers to the same thing. The terms might be mixed throughout the report.

⁴This is a simplification, but still holds true

known as a stale block, a block that is part of the chain but not part of the longest chain of blocks. Transactions in a stale block are not considered valid, and eventually they can be pruned (deleted) because they do not effect the future in any way. A stale block occurs if a new block is found in different parts of the network at almost the same time. Then the network will be split, each node tries to find the next block on the chain of whatever block they received first. In the case shown below the chain on the left "won" and the green block is now the longest chain.

The red block in figure 1.3 is what is known as an orphan block, that is, it has no known parent in the chain. This can happen if someone mines a block that is malformed or when building the chain for a new node and the blocks are received out of order.

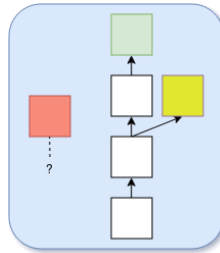

Figure 1.3: A diagram showing the longest chain, The green block is the latest block on the longest chain. The red block is a an orphan block, the yellow block is a stale block

1.2.4 Software

Just like how you can use regular money without knowing the underlying process and technology of banking systems for example, you can use Bitcoin without knowing the details of how it works. There is plenty of software that handles wallets, transactions etc for you.

1.2.5 Programmable transactions

Another feature that Bitcoin has, which makes it very versatile, is that transactions are programmable. As mentioned earlier the most common transaction is sending the money to someones public key. What really goes on here is that the person who wants to spend whatever money was sent to them has to prove programmatically that they own the private key related to that public key.

This is not the only type of transaction possible, Bitcoin has its own little programming language called **Script**. Any type of transaction that can be described in script is possible as a transaction. This is the basis for atomic swaps, payment channels and lightning network, which will be discussed in the following sections

1.3 Payment channels

One of the biggest problems facing Bitcoin is scalability. At the time of writing on-chain⁵ transactions is capped at about ≈ 7 T/s (transactions per second).[11] The throughput is limited by network propagation and a hard cap on block sizes, a block can only contain so many transactions before it is full. There are a couple of proposed solutions to this however, and one of them is connected payment channels

First off, a payment channel in Bitcoin is a type off trick using programmable transactions, were two users can open a bidirectional payment channel where an infinite number of

⁵See glossary

transactions could be trustlessly exchanged without using the blockchain.

A channel can be opened by one or both participants by using a funding transaction. The funding transaction requires the signature of both participants to spend and is transmitted to the blockchain. After that the participants in the channel exchange commitment transactions that represent exchange in money. Any of the commitment transactions could be broadcast to the blockchain whenever a participant wants to close the channel. Once a channel has been closed it cannot be used for further transactions. Mechanisms exist in the construction of these channels that make it so one participant can not cheat the system and spend money that does not belong to them.

Payment channels alone were not enough to fix the scaling problem however, as a payment channel only allows two parties to exchange unlimited transactions. A proposed extension to the payment channels is the lightning network.

1.3.1 Lightning network

Lightning network is a relatively recent development in the Bitcoin community. How to construct payment channels has been known about for a while. But in January of 2016 a white paper was released detailing a promising new extension.[21] It showed that with a few changes to the Bitcoin protocol a new type of payment channel could be opened that allows transactions to propagate through multiple channels.[21]

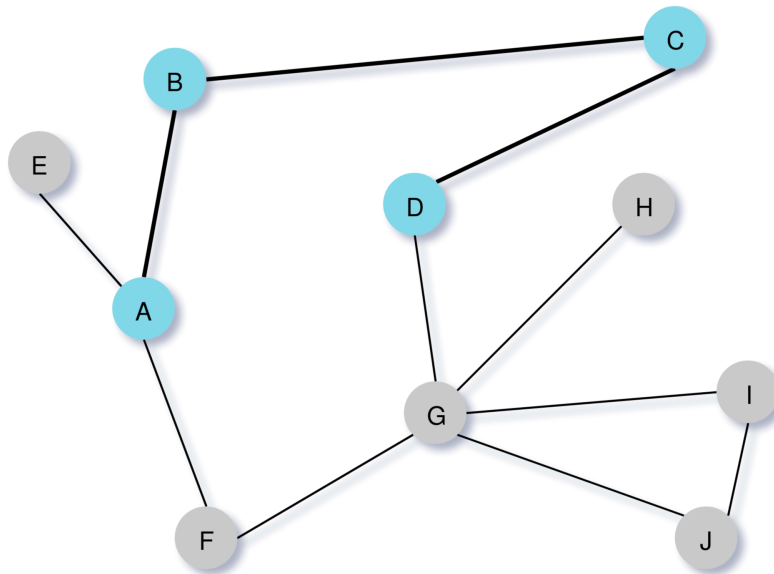

Figure 1.4: A basic overview of a Lightning network, each node represents someone and each edge represents a channel between two people.

Lightning network is really just a network of peers connected via payment channels. In figure 1.4 is an example. Let's say that Alice (node A) wants to send a transaction to David (node D) but they have no direct payment channel between them. With lightning network they can send the transaction via the peers that are between them, given that there is a path between the nodes, and that there is enough funds in all the channels between.

1.4 Atomic swaps

Another recent development in bitcoin is atomic swaps. Atomic swaps were first described by Tier Nolan in a post on bitcointalk.org on May 21, 2013.[12] A regular swap can for example be two parties exchanging currencies. Before, this could be done in person,

or via a trusted third-party handling all the transactions. Atomic swaps however is as the name implies atomic. Meaning that they either go through completely or no assets change hands at all, they are also completely trustless meaning that you do not have to trust the other party or rely on any third-party

Just like lightning network, atomic swaps use clever transaction scripts to achieve new functionality. Atomic swaps have been shown to be possible over lightning network in theory. Yet today no standardized protocol exists, neither is it a part of the lightning network as it exists today.

1.5 The goal of the project

The main goal of the project is to experiment and perform as many types of atomic swaps as time allows with the purpose of developing a proposal on how future implementations of atomic swaps could be standardized, in regards of protocol and software.

In regards to on-chain atomic swaps, there is no protocol to update as it relies entirely on the largely unchanging logic of the bitcoin consensus protocol. Any proposed changes would be in regards to how existing wallet software could handle atomic swaps in the future if they ever become more mainstream.

Most lightning network node implementations follows a standardization called the BOLT (Basis of Lightning Technology). The BOLT specification has intentionally left spaces open in it's a protocol to allow for future extensions, this gives a good opportunity to speculate and propose changes and additions to the specification that could make atomic swaps possible with as little human intervention as possible.

Chapter 2

Bitcoin and Smart contracts

2.1 Bitcoin: a peer to peer electronic cash

As described in the title of the original white paper[23], Bitcoin is a peer to peer electronic cash system, which does not rely on any centralized third-party to verify the validity of any transactions or handling of transaction completion. Instead it is entirely decentralized and trustless. The mechanisms and mathematics that makes this possible are relatively recent discoveries in computer-science.

2.1.1 Network wide consensus

One of the main problems facing decentralized currencies before bitcoin was invented is the byzantine generals problem (Byzantine fault)[19]. This refers to independent agents in a system being unable to reach a consensus on what has transpired and what actions to take next. The problem can be imagined as the network being split, where one subsection of the network believes transaction order **A** is correct while another non-overlapping subsection thinks transaction order **B** is correct. How can this be resolved, and how will a new node joining the network know which order is the right one?

Bitcoin was the first cryptocurrency to properly solve this problem once and for all, with the help of something called proof-of-work. Proof of work originates from the slightly older idea of hashcash.[10]

Hashcash was/is a means to limit email spam and DDoS-attacks by a proof of work system. For example a sender could be required to produce a hash of message and nonce with a certain number of bits set to 0 at the start of the hash sequence. This (statistically) should take several attempts to produce. But correctness could be checked in a single step. Thus the hash sent together with the message could be considered proof of work. Because there is no known way to produce such a valid hash of a message without trying random combinations of bytes. Thus the only realistic way to have such a hash is if you worked for it [10]. Looking for a valid hash in this kind of proof of work systems is often referred to as **mining**.

Bitcoin used this proof of work concept for another purpose however. Rather than combating spam the proof of work mechanism is used for reaching consensus. When ever a new block is added to the chain it needs to meet a certain proof of work requirement, called difficulty. This difficulty is set so that it should take the combined hashing power of all participants on average 10 minutes to find a valid hash of the next block in the chain.[23][16]

There is a term called longest proof of work in bitcoin, this refers to the chain of blocks that has the most hash-power supporting it. The chain with the most work done is statistically

the one with the most participants. As long as 51% or more of the participants in the network are honest the longest chain can be trusted. So any new members can accept the chain with most work as the truth.[16]

Splits

Contention for the longest chain can arise if a new block is found in two different parts of the network at (almost) the same time. This is not a problem and will eventually be resolved. If you imagine two blocks (**A1** and **B1**) being mined in different parts of the network with the same parent block and half the network got **A1** first and the other half of the network got **B1** first. While the entire network will accept all valid blocks they will only mine towards continuing the chain on the block they received first. So if a new block **A2** with the parent block **A1** is found first the chain formed by block **B1** will be considered invalid and the network continues the chain on the **A** side.[16]

Such contention is called a split, or a fork, and happens naturally once every week or so. As explained they will eventually resolve themselves. The split becomes increasingly more unlikely to survive the longer it goes on. To begin with it is unlikely that a new block will form a split in the first place, and for the split to survive another block both new chains will have to receive a new block at almost the same time.[16]

So what happens to the transactions that were contained in the invalid chain **B1** in the example above? As that chain no longer is the longest it is not accepted as valid by the bitcoin network. This might sound scary, but it is not as big of a problem as it sounds. First of splits happens rarely, and two blocks that are mined in parallel often contains more or less the same transactions, as inclusion is based on the fee. Common operation when a block goes stale is to re-add the transactions that were not in the other block into the memory-pool, so the transaction is very rarely lost. If it is very important that a transaction is not lost under any circumstance you will have to wait for confirmations before accepting it as payment. Confirmations on a transaction is a count of how deep down the transaction is in the blockchain, for example 6 confirmations means that the transaction is 6 blocks deep in the blockchain. The deeper the transaction is the more likely it is to not be considered invalid in the future.

In common bitcoin lingo there is no difference between a split and a fork. But in this report a **split will referred to as one occurring unintentionally** and a **fork being intentional** just so there is no confusion

Forks

Forks happen when there is a disagreement in the bitcoin community when it comes to protocol and consensus. The most famous fork in all of cryptocurrency occurred on **1st August 2017** and was caused by a conflict regarding the size of blocks. How bitcoin will scale to world-wide use has always been a hot debate in the bitcoin community, the majority seeks to scale bitcoin via second layer solutions such as payment channels, lightning network and side-chains. However there were those who disagreed, and instead wanted the network to handle more transactions by making the blocks larger at cost of centralization.

How long was the longest split?

The longest splits that occurred by chance were 4 block long and has occurred at least at 3 different occasions.

The longest split ever was caused by an update to the bitcoin core reference implementation (**0.8.0**) that rejected a block that the other implementations did not reject, the nodes accepting the new block kept building on it while those who had updated built on a different chain. The split lasted for 52 blocks before it was resolved.

A change in the blocksize requires the entire network to upgrade to the new protocol rules, but the block size increase was not accepted by enough nodes. So the group decided that a fork was the only way to resolve the issue. So as mentioned on 1st August 2017 the first block was mined on the new chain.[20]

The new chain got the name **Bitcoin cash** (bcash) while the main chain still is called just **Bitcoin**. Most miners and node owners stayed with Bitcoin, but a fraction jumped ship and started working on bcash instead. Today both chains runs along side each other, co-existing.[20]

Forks are considered a valid way to vote on what consensus rules and protocol changes should be made. When a change is planned to be made in the chain those who disagree can branch off and follow the old rules. Thus in a way everyone gets their way. You could even branch off on your own forked-chain alone. The main problem for those forking is that most vendors and users still consider the largest (most users, most developers, largest price, etc...) chain to be the valid one.

Soft and hard-forks

As mentioned forks happens when there is disagreement in the network regarding the consensus rules. When a fork happens where two sub-groups of the entire network essentially follows two different blockchains, that is what is known as a hard-fork. There is another type of fork however called a soft-fork. Every change in consensus rules are not incompatible with previous rules, in fact an update to the protocol could be made to be backwards compatible with software running on an older protocol.[16]

An example of a soft-fork is the Segregated Witness update (see section 2.5). The changes it brought was still compatible with nodes that had not updated, transactions using segregated witness appears like a "anyone can spend" transaction to nodes running the older protocol. Soft-fork is a bit of a misnomer considering that there is no actual fork, as in the blockchain remains unforked.[16]

Not all updates can be made as soft-forks, a good example is changes in block size. As any change to that could never be compatible with older nodes.

2.2 Elliptic-curve cryptography & ECDSA

As covered in the introduction, Elliptic-curve cryptography (**ECC**) and ECDS (Elliptic curve digital signature) is a fundamental building block of bitcoin. Elliptic curve cryptography relies on intractability of calculating the discrete logarithm of a elliptic curve element with respect to a publicly known base point.[22][23][16][24] Or put another way: It is easy to calculate elliptic curve multiplication with multiplicand n . But calculating n from the resulting point is considered infeasible with sufficiently large curves and multiplicands.[16]

An elliptic curve is defined by the equation $Y^2 = x^3 + ax + b$ and six domain parameters $E(p, a, b, G, n, h)$. [25][24] \mathbf{p} is the field that the curve is defined over, this is usually a very large prime number. The curve being defined over a field simply means that the points on the curve fall within $[0, p]$ rather than within the real numbers \mathbb{R} . In other words the curve is defined over the field \mathbb{F}_p . \mathbf{a} and \mathbf{b} are whatever number you put into the equation. \mathbf{G} is the generator point, that is the point on the curve that will be used in point multiplication later. \mathbf{n} is the order of \mathbf{G} . What that means is that n is the largest number that G can be multiplied by before a point at infinity is produced. n pretty much tells you the limit on how many points on the curve that can be generated from G . \mathbf{h} is the co-factor of the curve. It can be calculated as follows: $h = \frac{1}{n}|(E(\mathbb{F}_p))|$, where $|(E(\mathbb{F}_p))|$ is the order/cardinality of the group of points possible on the curve over field \mathbb{F}_p . n is derived from G , G and p should be chosen in such a way that $h \leq 4$, preferably $h = 1$.

These domain parameters can be chosen manually or you can use predefined parameters. Elliptic curves that used predefined domain parameters are called named-curves. The named curve used by Bitcoin is called **Secp256k1**.[\[25\]](#)[\[16\]](#)[\[23\]](#)

2.2.1 Secp256k1

Secp256k1 is defined with the following domain parameters (hexadecimal):

$p = \text{FFFFFFFF FFFFFFFF FFFFFFFF FFFFFFFF FFFFFFFF FFFFFFFF FFFFFFFF FFFFFFFC2F}$

or alternatively:

$$p = 2^{256} - 2^{32} - 2^9 - 2^8 - 2^7 - 2^6 - 2^4 - 1$$

$$a = 0$$

$$b = 7$$

$G = (\text{79BE667E F9DCBBAC 55A06295 CE870B07 029BFCDB 2DCE28D9 59F2815B 16F81798,}$
 $\text{483ADA77 26A3C465 5DA4FBFC 0E1108A8 FD17B448 A6855419 9C47D08F FB10D4B8})$

$n = \text{FFFFFFFF FFFFFFFF FFFFFFFF FFFFFFFF BAAEDCE6 AF48A03B BFD25E8C D0364141}$

$$h = 1$$

2.2.2 Math on the elliptic curve

Two mathematical operations needs to be defined to operate on the elliptic curve: addition and multiplication, as they are defined by **SECG** (Standards For Efficient CryptoGraphy). In their paper: SEC 1: Elliptic curve cryptography.[\[24\]](#)

Point addition

Let's say you have two distinct points P and Q that both fall on curve $E(p, a, b, G, n, h)$ ($Y^2 = x^3 + ax + b$).

$$P + Q = R \Rightarrow (X_P, Y_P) + (X_Q, Y_Q) = (X_R, Y_R)$$

$$X_R = \lambda^2 - X_P - X_Q$$

$$Y_R = \lambda(x_P - X_R) - Y_P$$

where λ :

$$\lambda = \frac{Y_Q - Y_P}{X_Q - X_P} \mod p$$

Point multiplication

If P and Q are coincident, meaning that they have the same coordinates the equation is slightly different.

$$P + Q = R \Rightarrow P + P = R \Rightarrow 2P = R$$

This could be seen as P being multiplied with scalar 2. Most of the equation is the same as with addition, the difference is that:

$$\lambda = \frac{(3X_P^2 + a)}{(2Y_P)} \mod p$$

Faster multiplication with large scalars

Take $xP = R$ that could be calculated by summing P x times:

$$\sum_{n=1}^x P = R$$

This might work fine for smaller numbers but for a very large number, like $x = 2^{100}$, it will take infeasible amount of time to calculate. Luckily there is a convenient short cut that you can take called double and add.

First remember that: $P + P = 2P \Rightarrow 2P + P = 3P \Rightarrow 4P = 2(2P) \Rightarrow 8P = 2(2(2P))$

Lets say $x = 200$ in binary terms this could be written as $x = 128 + 64 + 8$ or $x = 2^7 + 2^6 + 2^3$ thus $200P = R$ could be written as

$$2^7P + 2^6P + 2^3P = R$$

which can be expanded to:

$$2(2(2(2(2(2(2(2P)))))) + 2(2(2(2(2(2P)))))) + 2(2(2P))$$

This looks more cumbersome but now instead of 200 calculations you only have to do 19. Or more exactly instead of 200 elliptic-curve additions you have to do 3 elliptic-curve additions and 16 elliptic-curve multiplications

2.2.3 Private and public key

Just as RSA cryptography, ECC relies on public-private key encryption and signatures. The public key can be shared freely to everyone, while the private key should, as the name implies, be kept private. Each unique private key has a corresponding public key, through mathematics it can be proven that someone holds the private key paired with a certain public key, without actually revealing the private key.[16][25]

In ECC a **private key is a really large number**. Imagine you have curve $E(p, a, b, G, n, h)$ and you want to generate a brand new private key k . k could be any number between 0 and n . Any $k > n$ will produce the exact same public key so that will not work. **A public key in ECC is represented by a point in 2D space**, more specifically a point that falls on the curve.[16] To generate a public key P from a private key k you perform $kG = P$ as described in the section above.[24][25]

Compressed key

The public key is quite large, with two 256-bit numbers representing coordinates. But there is a clever trick we can use to compress the size of the key. Take the **Secp256k1** curve for example ($Y^2 = x^3 + 7$). It is mirrored around the x-axis, meaning that for each x value there are two possible y values. Thus a public key can be represented by only its x value plus a prefix telling you which resulting y -value to choose.[16]

Note that because y and x is over \mathbb{F}_p there is no negative value, instead the y value is referred to as even or odd.

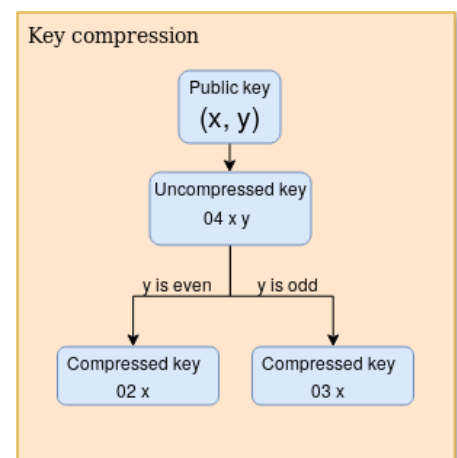

Figure 2.1: How to compress the public key in ecc

2.2.4 ECDSA

The main usage of ECC in cryptocurrency is for proving ownership of coins.[16][23] The proof relies on elliptic curve mathematics like before. Lets say **Alice** has a message m and want to send it to **Bob** and also prove that the message came from her. First of let's establish some variables: k_A is the private key belonging to Alice, and from it the public key P_A was generated. Bob knows P_A but not k_A

The signature generation and validation are as described by **SECG** (Standards For Efficient CryptoGraphy). In their paper: SEC 1: Elliptic curve cryptography.[24]

Signing

First calculate the hash of the message:

$$e = \text{HASH}(m)$$

If e has a bit-length (numbers in binary representation) that is longer than the bit-length of order n of the curve used. e has to be trimmed down so that the bit-lengths match

Select a cryptographically-secure random number z that falls in the range $[1, n - 1]$ and calculate a new curve point: $(x_1, y_1) = z \times G$

Calculate r and s such that: $r = (x_1 \bmod n)$ and $s = (z^{-1}(e + r \times k_A) \bmod n)$. if either r or s ends up being 0, generate a new z and try again.

The signature will be the point $(r, s) = S_A$.

Signature validation

If **Bob** wants to verify that it was actually **Alice** that signed the message m . He first has to do a sanity check on the signature S_A to make sure that it is a valid point on the curve and that s and r is within the range $[1, n - 1]$ etc...

Calculate the hash e of m the same way as it was done during the signing process. Calculate

$$w = (s^{-1} \bmod n)$$

and

$$u_1 = (ew \bmod n)$$

$$u_2 = (rw \bmod n)$$

From u_1 and u_2 calculate the point $(x_1, y_1) = u_1 \times G + u_2 \times S_A$

The signature is valid if and only if $r = x_1 \bmod n$

2.2.5 Addresses

While using Bitcoin normally you rarely interact with the public keys directly, instead you mostly see and use something that is called addresses.[16] For example if you want to send money to someone you use their bitcoin-address (see section 2.4.2). What the address really is, is just a obfuscated representation of a public key.

To transform a public key to an address you first hash it using **SHA256** then hash the result of that with **RIPEMD160**, this entire process is called **HASH160**. After doing **HASH160** you encode the resulting bytes in **Base58**, this is your address.[16]

$$\begin{aligned}\text{HASH160}(P_A) &= \text{RIPEMD160}(\text{SHA256}(P_A)) \\ A_A &= \text{BASE58}(\text{HASH160}(P_A))\end{aligned}$$

For example:

Compressed public key:

03b2319bf63ca8959794f79056283150f1b49d577b2c48bd9e4a18d616e6f99bb4

Hash160 of public key:

76a9147ecfe7db089f521c3f49de0ee866f8e0fee97d1788ac

Base58 of public key hash (Address):

ms5UVmKaaz8kiL7DbMA1NG3t6T4C4GmGzG

2.2.6 Homomorphism

Elliptic curves has a attribute called homomorphism. It will not be covered in depth, but what it can be used for is that two public keys (P_1, P_2) can be combined to form a third public key (P_R). If P_1 and P_2 was generated with corresponding private keys k_1 and k_2 then they can be combined to form the private key that generates P_R (k_R).[\[22\]](#)[\[8\]](#)

There are several ways of calculating a new homomorphic key, this is the one used in later implementations:

Let's say you have private key k with corresponding public key P . And another temporary private key k_c with corresponding public key P_c . To generate the homomorphic public key (P_h) you can use the following equation (All the operations in equation [2.1](#) below are in elliptic-curve addition and multiplication, The second ([2.2](#)) uses regular operators):

$$Generate(P, P_c) = P * SHA_{256}(P||P_c) + P_c * SHA_{256}(P_c||P) = P_h \quad (2.1)$$

You now have Public key P_h . To figure out the Private key correlated with this public key you do the following equation:

$$Resolve(k, k_c) = k * SHA_{256}(P||P_c) + k_c * SHA_{256}(P_c||P) = k_h \quad (2.2)$$

Revocation keys

Imagine Alice and Bob wanting a public key that neither hold the private key to, that could be revealed at a later date. Alice holds the key set (k_A, P_A) , and Bob has the set (k_B, P_B) . Bob creates another key set (k_T, P_T) and sends P_T to Alice.

Alice generates a new public key (P_R) from P_A and P_T with equation [2.1](#). Now the public key P_R could be used for whatever purpose needed, even though neither party knows the private key k_c at this point as calculating it requires both k_A and k_T and neither party holds both. At a later date Bob could reveal k_T to Alice, she could then use equation [2.2](#) to determine k_R .[\[8\]](#)

This method is used later in a concept called revocable deliveries, see section [2.6.2](#). In that case (k_T, P_T) key set would be called commitment point keys, and (k_R, P_R) would be called revocation keys.[\[8\]](#)

2.3 Script

Script is the name of the programming language used in Bitcoin and its derivatives. It was not used to write the Bitcoin implementation but rather it is what makes transactions

in Bitcoin so versatile. This section however will not focus on where or how Bitcoin uses Script, but rather on how Script itself functions.

Script is a forth-like stack based language that is not turing-complete.[\[5\]](#)[\[16\]](#) Turing-completeness means that a language can do anything that the imaginary turing-machine could do, in other words it basically means is that the language can do any mathematically sound operation. Script is **NOT** turing-complete on purpose, a good example is loops, in most languages there is some sort of structure that allows for a piece of code being executed repeatedly. In Script this is strictly disallowed, as it has neither for-loops or while-loops. This means that any given script will execute within a well defined deterministic time-span, and can never go on forever.

As mentioned earlier. Script is a stack-based language. That means that as the language executes it uses a stack to store data and variables. Do not confuse the term with the heap and stack from regular programming language discourse. In script there is no heap, instead the stack is the only form of memory, and it acts just as you would expect from a stack, to add a value you have to push it to the stack and to read a value you have to pop it from the stack.[\[5\]](#)[\[16\]](#)

The language itself is quite basic. It relies on operation codes (op codes) the size of a single byte. Most operations pop values from the stack, does something with the values, then pushes the result back on the stack. When Script is written out on paper many op codes and values are excluded, because they are implicit. For example:

```
OP_PUSHDATA1 4 FFFFFFFF
```

This operation pushes 4 bytes to the stack, the bytes have the hexadecimal value FFFFFFFF. But usually when this operation is written out it is shorten to just:

```
FFFFFFF
```

Whenever a hexadecimal value appears in the code it is implicit that that value is pushed to the stack in the form of bytes. Here is another program:

```
4 5 OP_ADD 9 OP_EQUAL
```

This simple program will push 4 and 5 to the stack, `OP_ADD`[\[5\]](#) pops two values from the stack (4 and 5) adds them together and pushes the result back on the stack. Then a 9 is pushed to the stack. `OP_EQUAL`[\[5\]](#) pops two values from the stack and pushes a 1 if they were equal, 0 otherwise. In this case a 1 will be left on the stack as $4 + 5 = 9$. Figure [2.2](#) visualizes what happens at each step of execution. There are other cases where the verify op-code is combined with other instructions.

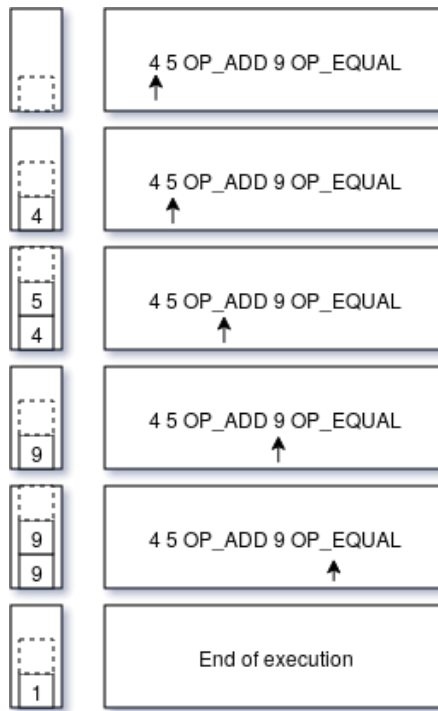

Figure 2.2: Execution of simple program, to the left is the stack, to the right is the program with execution pointer

2.3.1 Complex operations

There are some operations in Script with slightly higher complexity, which do not act like the others. One of them is `OP_VERIFY`, this will perform a verify check on the script. It will pop one value from the stack, and if that value equates to false execution will end immediately and the entire script will be marked as invalid (see section 2.3.2).[16][5] If the value equals true execution will continue where it left off. Some operations are combinations with the verify check, like for example `OP_EQUALVERIFY`. This is equal to writing `OP_EQUAL OP_VERIFY`, meaning that it first does an equal check then verifies the result.

There are several operations for checking signatures. These are not so complex in terms of what they do in the script. Their implementation is quite complex however. They rely on outside information that is not present in the script to check the validity of a signature.[5][16] The two most used are `OP_CHECKSIG` and `OP_CHECKMULTISIG`. These will not be covered in full in this section as they are more related to transactions so see section 2.4 for a full explanation.

2.3.2 Valid and invalid scripts

At the end of execution a script is marked as either valid or invalid. A script is invalid for the following reasons[16]:

- The stack is empty
- There are more than one values on the stack

Bug in Script

An interesting bit of trivia is that there is a bug in the language implementation. More specifically with the operation `OP_CHECKMULTISIG`. The bug makes it so this operation pops one more value from the stack than it is supposed to. This was not discovered until the network had been running for a while. It can not be easily fixed as it is now a part of the consensus rules. All implementations of Bitcoin node has to implement the bugged version of this op code otherwise consensus on the validity of transactions will break. A fix to this bug would require a hardfork, see section 2.1.1, so far it has not been done as it is considered to be not worth the time and effort.

- The only value on the stack equates to false
- A VERIFY check fails sometime during execution.

A script is valid if and only if there is one value on the stack, and it is not equal to false.

2.4 Transactions

Transactions in Bitcoin are not as straight forward as you might expect a transaction to be. A transaction contains a list of inputs and a list of outputs as well as some metadata like version number and lock-time.[7][16]

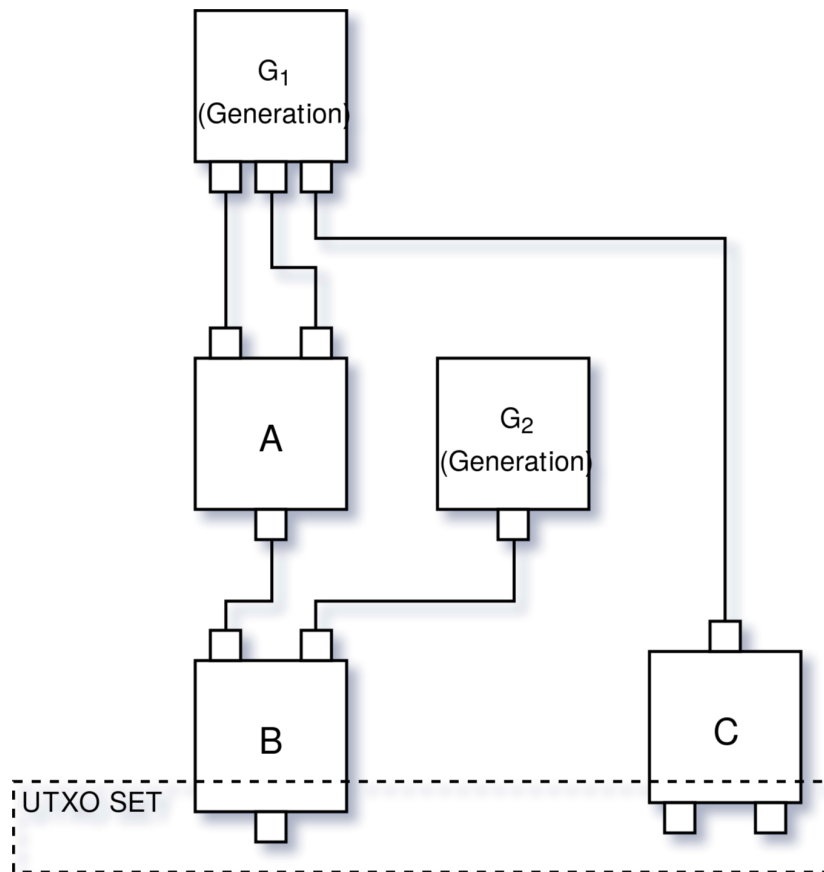

Figure 2.3: 4 example transactions and how inputs are connected to outputs

In simplified terms an output could be seen as the destination of a transaction, in other words it says how much and to whom the transaction is sent to. An input is a reference to a previous output. The inputs take the money from the outputs they reference and that money is used to fund the new outputs.[16][7]

The inputs and outputs is where Script comes into the picture. Both outputs and inputs contains an incomplete script, together however they complete the script. The script in an output could be seen as a challenge, and the script in the input is the response. When a transaction is tested for validity the input script is appended to the script in the output and is executed. If the script comes out as valid the transaction is also valid.[16][7] Here is a basic example: Let's say Alice wants to send a transaction to whoever can answer the equation $4 + 3$. Her transaction output would contain the script:

```
4 3 OP_ADD OP_EQUALS
```

If this is executed as is it is invalid. But let's say Bob knows the answer to the equation

he can then create a new transaction where the input contains the script:

7

Just as before this script is not valid by itself. But then the transaction is checked for validity the input will be appended to the start of the output script forming the following:

7 4 3 OP_ADD OP_EQUALS

Which is a valid script, thus Bobs new transaction is also valid and he may spend the money as he see fits.

Obviously most transactions on the Bitcoin blockchain are not this simple. The most common form of transaction contains a script called P2PKH which stands for Pay to public key hash. Before we can go into details on this one however we first need to know about how signatures and sighash work in script and transactions.

2.4.1 Signatures and sighash

Section 2.2 covers public keys and signatures in depth.

Perhaps the most important operation in script is the `OP_CHECKSIG` operation and its cousins. `OP_CHECKSIG` pops two values from the stack, if the script is correctly implemented these two values should be the public key and a signature created with the private key that correlates with mentioned public key

The question is: what is signed when the signature is created? Broadly speaking it is the hash of the transaction that is trying to spend the output, this is not entirely accurate however.[16] Appended to the signature that is a flag called **sighash** (Signature hash). The value of sighash tells the script interpreter what hash was signed during the creation of the signature.[6] There are 4 types of sighash implemented:

SIGHASH_ALL

This can be considered the default sighash, if it is not stated otherwise it can safely be assumed that this type was used. This simply means that the entire transaction is signed with all outputs and all other inputs.

SIGHASH_NONE

This one signs the transaction but without the outputs, it could be thought of as "I do not care where the money goes".

SIGHASH_SINGLE

All outputs are removed except the output with the same index as the input that is being signed, then that transaction is signed. This could be thought of as "I do not care about any other outputs to this transaction as long as this one remains as is".

SIGHASH_ANYONECANPAY

Signs the transaction with all the outputs but none of the other inputs. This basically means "The money has to go here, but I do not care if someone else want to fund this transaction also"

2.4.2 Pay to public key hash (P2PKH)

P2PKH is as mentioned the most common form of transaction.[16] This transaction can be thought of as paying to somebodies address. In other words the output of this transaction contains a script where the one who wants to redeem it must prove that they own the private key which created the public key the address is referring too. This is what the script looks like in the output:

```
OP_DUP OP_HASH160 <public key hash> OP_EQUALVERIFY OP_CHECKSIG
```

As mentioned already executing the script in the output by it self does not make any sense, especially now when the very first operation `OP_DUP` tries to duplicate the top element in the stack. But at execution the stack will be empty. Anyone wanting to spend this output would construct a transaction with the input script on the following form:

```
<signature> <public key>
```

When the input and output is executed together the process goes like this:

1. First the signature and unhashed public key is pushed to the stack.
2. The public key is duplicated (there are now one signature and two public keys on the stack).
3. The top public key goes through the HASH160 process making it a hashed public key.
4. The hashed public key from the output is pushed on the stack, at this point the stack has the following elements (`<signature>`, `<public key>`, `<hashed public key>`, `<hashed public key>`).
5. `OP_EQUALVERIFY` checks if the top two elements is equal and verifies the result, What basically has been done is is that the script checks if the public key provided in the input script is equal to the hashed public key given in the output script.
6. At this point the stack has the following elements: (`<signature>`, `<public key>`). `OP_CHECKSIG` pops these from the stack and checks if the signature is valid.

In the early days of bitcoin you payed directly to public keys instead of hashed public key. The reason the hash part was added at all has to do with extra security. If an exploit is found in elliptic curve cryptography that makes it so someone could calculate the private key from a public key then all unspent outputs would be at risk of being stolen. With the hashed public key the actual public key is not revealed until the output is spent, and then it is too late for it to be stolen. This of course requires that everyone uses a different public key for every transaction, which is the standard today.[7]

2.4.3 Pay to script hash (P2SH)

Pay to script hash is slightly newer and a bit more complex to understand. Instead of paying to someones address, you pay to a script, this was initially proposed by Gavin Andresen in 2012.[3] Let's say Alice has partial script S , that can be solved with the partial script K . She can then hash S and get H_S . She then creates transaction with an output containing the following script:

```
OP_HASH160 <HS> OP_EQUAL
```

If Bob wants to redeem this transaction he first has to know the script and how to solve it. This is how the transaction input would look like:

K <S>

The execution of the combined input output script is not straight forward as most scripts are. This is the process:

1. The K part of the script is executed as usual. This pushes or does whatever it needs to do to make K + S a valid script.
2. The partial script S is pushed to the stack in the form of bytes.
3. This is where the execution takes a strange and not so intuitive path, as you will see. First the script is hashed with the OP_HASH160 operation.
4. The script hash from the output is pushed on the stack.
5. OP_EQUAL checks if the top two items on the stack are equal. If they are it means that the script S provided in the input is the correct script.
6. Unique to P2SH, the execution goes back to the original script S that was pushed to the stack in stage 2. And executes it together with whatever K pushed to the stack. This script also has to be valid.[3]

If all stages are executed without error the redeeming transaction is valid.

P2SH was developed to resolve the difficulties in making complex transaction scripts and make them as simple as paying to an address. What P2SH basically means is "pay to a script matching this hash, a script that will be presented later when this output is spent"[16][3]

2.4.4 Timelock and sequence

Since the start of bitcoin; transactions has had two fields in them called **nTimelock** and **nSequence**. The timelock variable stopped a transaction from being included in a block until a certain unix-timestamp or a certain blockheight¹ had passed. The sequence field is part of each input into a transaction, it's original purpose was to give users a mechanism for updating a transaction that were still in the transaction-pool. Miners were supposed to include the transaction version with highest sequence number, this however was unenforceable, as there is no way of knowing which transactions were in the transaction-pool of the miner at the time of block creation. So nSequence became mostly defunct and saw little use.

To make timelocks more versatile and more easily enforceable Peter Todd proposed an addition to Script, a new op-code that verifies that the correct timestamp is set, OP_CHECKTIMELOCKVERIFY.

As timelocks only allows for absolute wait time, like for example: "this transaction can only be spent after 10th June 2019". Mark Friedenbach et al. proposed in 2015 to add an additional op code to Script that can check for relative time passage as well, OP_CHECKSEQUENCEVERIFY.

OP_CHECKTIMELOCKVERIFY

There is an operation in Script called OP_CHECKTIMELOCKVERIFY, what it does is that it compares the timestamp or blockheight that is on the stack and compares it to the timestamp that is in the transaction trying to spend the output that this op code is part of.[16][4][5][7]

¹Blockheight is the number of blocks on the current chain

OP_CHECKSEQUENCEVERIFY

OP_CHECKSEQUENCEVERIFY is a lot like the previous one except it it deals with relative time.

Let's say you have two transactions transaction T_A and transaction T_B , T_A is included in a block on the blockchain. If T_B tries to spend one of T_A outputs and has that specific input marked with a sequence of 10. It means that T_B can not be included in the block chain until T_A is at least 10 blocks deep in the blockchain.[16][1][5][7]

OP_CHECKSEQUENCEVERIFY enforces this in the output. If T_A has 10 OP_CHECKSEQUENCEVERIFY, then if T_B tries to spend that output it has to be at least 10 blocks deep.

2.5 Segregated Witness

Segregated witness (sometimes called just segwit) is a relatively recent addition to bitcoin. A witness in cryptography is a proof of knowledge, for example a signature that acts as proof that whoever created the signature knows the private key that created a certain public key. A signature can also act as proof that the signer knew the content of whatever data that was signed.[16][24]

In bitcoin the script in each input is the witness, and segregated witness means that the witness part of the transaction is separated from the transaction. The witness is still sent with the transaction when broadcasting, but it is no longer part of the transaction structure.[16][2]

The reason for this change has to do with malleability. If a transaction still has the witness data it can be manipulated in millions of ways, and all these manipulated versions will all be valid. Let's look at an example, If a transaction has the following input script:

```
<signature> <public key>
```

A malicious actor could manipulate the script like this for example:

```
1 OP_DROP <signature> <public key>
```

The script is still valid.² Witness manipulation is not a security flaw in terms of monetary loss as the outputs can not be manipulated without breaking the signatures. What is changed however is the txid. The txid is used to identify the transaction, it is the hash of the entire transaction, you could imagine Alice sending money to Bob, Bob manipulates the transaction so that the txid changes, one of the manipulated transactions makes it into a block thus making all other versions, including the original, invalid, Bob got his money but he can now tell Alice that he did not. Alice tries to find her transaction in the blockchain with the txid she had but it can not be found.

Segregated witness was proposed by Eric Lombrozo et al. in December 2015 and activated via a soft fork on 21st July 2017[16][2], its purpose is to make the Bitcoin network ready for lightning network usage.[2] Segregated witness is not a necessity for payment channels and lightning network. But it does make it significantly safer.[2] A great example is the funding of payment channels. The funding transaction requires the signature of both parties to be spent, to prevent a malicious actor from broadcasting the funding transaction and locking both participants money eternally both signs the initial commitment transaction. The commitment transaction of course use the id of txid of the funding transaction as reference. With malleable transactions a malicious actor could modify the funding transaction and broadcast it. The commitment transaction would be useless as

²A transaction with that input script would be rejected in current implementation, but it shows the concept of malleability pretty well

its referenced txid does not exist.

As mentioned segwit separates the witness and transaction. This makes it so the witness is no longer part of the txid, making it effectively immutable. The witness data is stored separately to the blockchain and its byte-size is not counted towards the block size, making it so more transactions could fit in a single block; it does not make the storage requirement any smaller as the witness data still needs to be stored for validation.

2.6 Payment channels

A payment channel is a channel where transactions can be exchanged trustlessly on channels other than directly on the blockchain. This is what is usually referred to as off-chain transactions. In their most naive form a payment channel can simply be Alice and Bob exchanging promises of future transactions later. This however is not trustless and any of the parties could later withdraw from the promise without punishment (other than maybe loss of friendship and future trust).

To build a trustless payment channel there are several ways to go about as Script is quite versatile. The method that will be covered here uses a type of channel **funding transaction that requires the signature from both parties to spend**, and the channel balance is updated via special commitment transactions that spend the funding output. Each party in the channel has their own version of the commitment transaction. Whenever a commitment transaction is broadcast to the blockchain the channel is closed as the funding transaction can not be spent twice. To update the balance in the channel both parties create new commitment transactions and signs the other parties commitment transaction.[21][16] Let's take a look at a naive example:

2.6.1 The naive payment channel

Imagine Alice and Bob wants to open a payment channel between each other. They create a funding transaction and the initial commitment transactions. Let's say they both funded the channel with 1 Bitcoin each. The initial commitment transactions would then have one output paying 1 Bitcoin to Alice and one output paying 1 Bitcoin to Bob, let's call this commit (**C0**). The funding transaction is broadcast to the blockchain.

A bit later Alice buys one funny hat from Bob for 0.1 Bitcoins. To complete the transaction they create two new commitment transaction that pays 0.9 Bitcoin to Alice and 1.1 Bitcoin to Bob and signs them for each other, let's call this new commitment (**C1**). Any number of transactions could be exchanged this way. The channel could be closed by any one broadcasting their commitment transaction. This naive implementation of a payment channel has a fatal flaw however.

A payment channel needs some safety measures to be safe from malicious actors. The above example lacks a mechanism for preventing old commitment transactions from making their way into the blockchain and still paying the malicious party.. For example after the initial funny hat transaction above (**C1**) Alice could just broadcast the initial commit transaction (**C0**) and reclaim the 0.1 Bitcoins she spent. Bob would have no way of preventing this in this naive implementation.

2.6.2 Transaction flow diagrams

The transactions that are involved in making payment channels grows larger the more features that are added. To make it easier to understand, diagrams are used together with the descriptions. In Figure 2.4 a basic overview of the diagram-realm transaction is shown. Lines leading from outputs to inputs means that the connected input are spending

that output. Note that one output can be connected to several inputs but each input can only be connected to one output, of course an output can only be spent once, this will be clarified later. A question mark (?) in the broadcaster field indicates either that the sender is unknown or that who sends it is irrelevant.

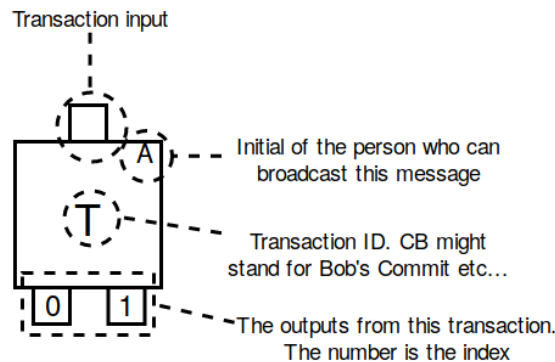

Figure 2.4: Different parts of a transaction as they appear in diagrams.

Payment channel with breach remedy

To prevent old transactions from being sent to the blockchain a new mechanism needs to be devised. This can be done via something called revocable delivery and breach remedy (Some times called just revocation). Instead of both parties holding the same commit. They each get an individual one that differs in its outputs.

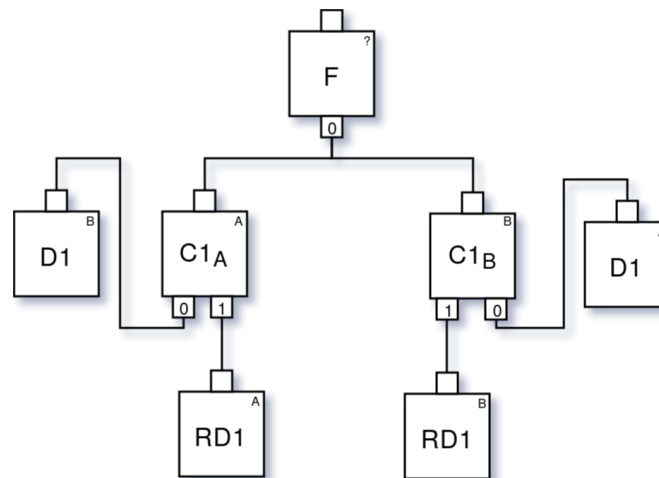

Figure 2.5: Payment channel, with commits using revocable delivery mechanism

Figure 2.5 shows how the payment channel appears after the first commitment transactions has been made. Let's say the channel is between Alice (A) and Bob (B) and the balance in the channel is 0.5 BTC for Alice and 0.5 BTC for Bob.

Let us take a look at the left side of this diagram. $C1_A$ is the commitment transaction on Alice's side of the channel. As with all commitment transactions it spends the funding transaction. It has two outputs. Output 0 sends 0.5 BTC to Bob completely unencumbered. Output 1 is a bit more complicated however. It pays into a revocable delivery contract worth 0.5 BTC.³ The contract is constructed with a relative time lock that allows Alice to claim her share of the money after x amount of time (relative to the broadcast

³The contract is a script, and it is paid to via P2SH

time of $C1_A$, often described in terms of blocks) or pays to whomever can sign using the pre-generated revocation keys (See section 2.2.6)

D1 is the transaction Bob uses to claim his money in case Alice decides to broadcast her commitment transaction ($C1_A$).

RD1 is the transaction that Alice uses to claim her money. The transaction has a relative timelock on it that makes it so it can not be broadcast until x blocks has passed since $C1_A$ was included in the blockchain. **From now on the relative timelock will be 100 blocks in all the following examples.**

The right side is identical, only that the RD1 and D1 relationship is reversed, meaning that Alice can claim her money directly and Bob has to wait.

If Alice wants to send 0.1 BTC to Bob they need to update the channel with new commitment transactions and then invalidate the old transaction. The transaction diagram will now look like figure 2.6

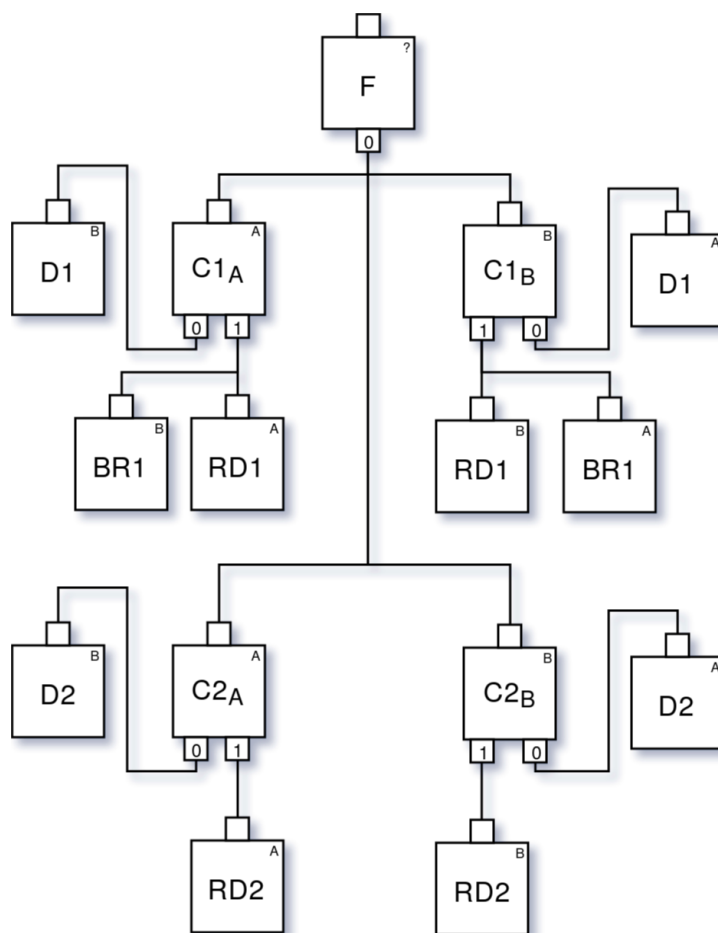

Figure 2.6: Updated payment channel, with breach remedies for old commitment transactions

Figure 2.6 shows the state of the channel after the new commitment transactions have been finalized. $C2_A$ is a lot like the previous commitment transaction with a few changes. The primary change is of course the channel balance, output 0 now has 0.6 BTC as value and output 1 has 0.4 BTC (Because Alice sent 0.1 BTC to Bob).

Another important update to the channel is the breach remedy. $BR1$ is the breach remedy for the first commitment transaction, its purpose is to prevent old commitment transac-

tions from being broadcast.[21] The breach remedy can be created after Alice has revealed the secret private key she used when creating the revocation key. Of course to prevent a new false breach remedy to be created for C_{2A} Alice uses a new revocation key for all new commitment transactions. If Alice tries to take back her money by broadcasting an old commitment transaction Bob can prevent it by broadcasting the breach remedy, this is possible because of the timelock on Alice's claim being time-locked.[21]

These are the steps taken whenever someone wants to send money in the channel (Under the assumption that commitment $n-1$ (C_{n-1}) was the latest commitment transaction in the channel), Alice is assumed to be the sender:

1. Both parties create new revocation public keys.
2. Alice creates the commitment on Bob's side (C_{nb}) using the revocation key from the previous step, signs it and sends it to Bob.
3. Bob creates the commitment on Alice's side (C_{na}) using the revocation key from the previous step, signs it and sends it to Alice.
4. Each party generates their respective Delivery and Revocable delivery transactions (D_n and BR_n)
5. Both parties reveal the secret used to create the revocation keys for the previous commitment transactions (C_{n-1})
6. From these revocation keys each party constructs the breach remedy (BR_{n-1}) for the previous commitment on the other persons side.

These steps can be repeated however many times until the channel is closed.

2.6.3 Naive payment network

The current form of our payment channel works very well as long as it is between just two parties. A very helpful feature would be to be able to send money to anyone without having a direct channel between you and that person, in other word the transaction jumps between any number of other channels before reaching it's destination. If we naively use the channel we have constructed in the previous section as is to send money over multiple jumps we would run into the following problem:

Imagine there being 3 people: Alice (A), Bob (B) and Cecil (C). Alice and Bob have a channel between each other and Bob and Cecil have a channel between each other. Making the following graph: A - B - C. Alice wants to send money to Cecil but they have no channel between each other. To solve this Alice asks Bob to promise to send x amount of money to Cecil if Alice sends x amount of money to Bob. In the perfect world Bob would be honest and this system of payment networking would work. In the real world however having to trust every node between you and the destination would cause problems with malicious nodes. There is nothing stopping Bob from taking Alice's money and never sending anything to Cecil.

The channel has to be extended further to allow multi-hop payments and still retain it's breach remedy feature. This is where Hashed Time Locked Contracts come into the picture.

2.6.4 Payment channels with Hashed Time Locked Contracts

A new mechanism needs to be added to our payment channel to enforce that multi-hop transactions actually make it all the way to their destination while at the same time still retaining the breach remedy mechanism etc...

This could be done by adding a third output to the commitment transactions. This new

output pays to a hashed time locked contract (**HTLC**).^{[16][21]} Before when a payment was made over a payment channel the amount was updated for each output representing a user in the channel. With the HTLC-output the amount sent is represented by the value of the HTLC-output.^{[21][8]}

A channel could be thought of as having three states: regular, unsettled, and settled. The regular state is the one described in previous sections, it's a channel with one set of active commits, the commit will not have any HTLC-outputs.^[21] A channel where the latest commits has a HTLC-output is considered unsettled. The unsettled state should only exists while there is uncertainty about whether the multi-hop transaction completed or not. You could say that **the HTLC-output only exists as a contingency**, if both parties cooperate the channel can return to regular state with the channel balances updated accordingly, if the parties cannot agree or for some reason will not cooperate the channel should be close as soon as possible, as to why we will get to that.^[21] A channel reaches a settled state when both parties decides to close the channel, it is done by creating one last pair of commitment transactions but without any revocable deliveries. After a channel is settled no further transactions could be exchanged in it safely as the mechanism for preventing old transactions from being broadcast has been removed, instead the commitment transaction should be broadcast and the channel properly closed.^{[21][8]}

To understand the HTLC-output you first need to understand the general mechanism that is used to ensure that multi-hop transactions work.

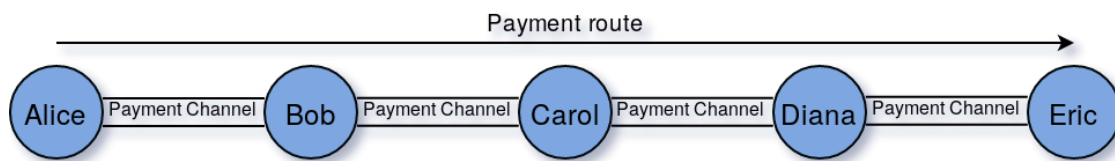

Figure 2.7: An overview of a network formed by payment channels

The principle used for multi-hop transactions is a lot like the one used for on-chain atomic swaps. It relies on revealing a secret pre-image⁴ of a hash within a certain time limit. Using the diagram in figure 2.7 as example. Alice wants to send money to Eric. But they have no direct channel between each other. To make this work Alice asks Eric for a hash of a secret, let's call this $H = SHA256(R)$. For now Eric holds on to R and only sends H to Alice.

For the money to reach Eric, Alice needs to go via Bob. To do this Alice requests from Bob that they make a new commitment transaction with one HTLC output. The amount in the output should be equal to to whatever amount Alice want to send to Eric. The promise here is that Bob will get this money only if he can prove that he has the pre-image to H. Bob does the same with Carol. This continues until an updated commitment reaches Eric. Eric can then send the pre-image R backwards through the chain until it reaches Alice.

⁴See glossary

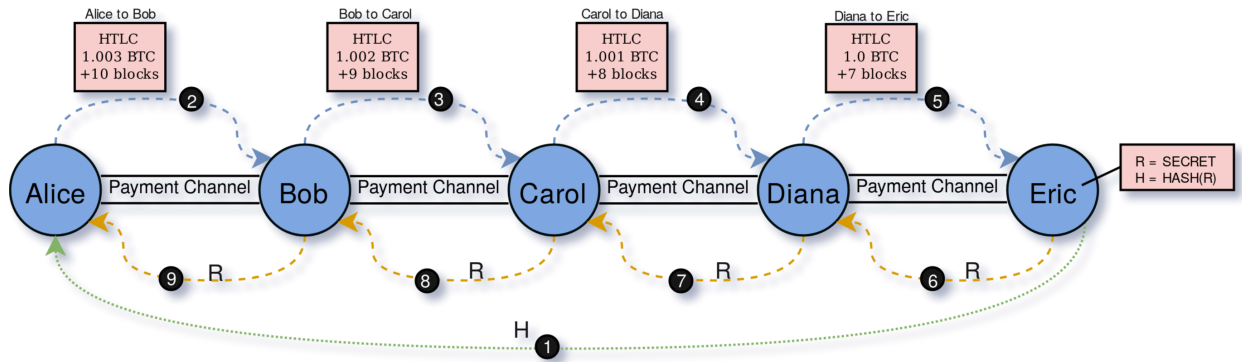

Figure 2.8: All the steps taken in the payment network

Earlier it was mentioned that the HTLC output only existed as a contingency, when Bob can prove to Alice that he knows the pre-image R , and can claim the money in the htlc-output by closing the channel, Alice has no reason to not update the channel with correct balances in Bob's favor. Thus the channel returns to a regular state with no htlc-outputs and all previous commits are revoked. This is done for all channels between Alice and Eric. If a party will not co-operate in the chain the channels to that person will have to be closed, this is the only case where the htlc-outputs are actually spent. There is no risk of monetary loss, closing channels is generally something that should be avoided if not absolutely necessary.

2.6.5 HTLC in more detail

The HTLC script is a bit different depending on what side you are on in the channel, in other words the HTLC in the commitment of the sender is different to the one on the receiver end. What they both have in common however is the three possible outcomes. Let's call these paths **HTLC timeout**, **HTLC execution** and **HTLC breach remedy**.

HTLC execution can be considered to be the main path and the one that is taken if everything goes as planned. Let's take a closer look at what happens in the channel between Alice and Bob in figure 2.8. Bob knows the secret R because Carol sent it to him. Under normal circumstances Bob would prove to Alice that he knows the secret R , Alice would accept and the channel would be updated to reflect the transaction taking place. But for the sake of example let's say that Alice is uncooperative and does not want to give up the money she just sent to Eric. Bob should then close the channel with Alice and claim his money in the HTLC output by providing a input containing the pre-image (R) and required signatures.

HTLC timeout is the path taken in the case where Bob never received the pre-image (R) from Carol. In this case the money should be refunded to Alice. Under normal circumstance Bob sees that Alice can claim the money and thus updates the channel to reflect the refund. In the case where Bob refuses to cooperate Alice can close the channel after the timeout has passed. This time no pre-mage is needed, only the signatures from both channel parties.

HTLC breach remedy pays the money directly to the party that did not send an old commitment transaction. The breach remedy path is redeemed by providing a correct signature with the revocation key.

The second-level HTLC is a necessary second part of the HTLC output. Whenever a HTLC-output is spent by the same person that broadcast their commitment transaction it has to lead into a second-level HTLC script, this is enforced by the HTLC script requiring the signature from both parties depending on what side of the commitment tree you are

on. The second-level HTLC script is fairly basic, it has two outcomes. Either the spender has to wait x amount of blocks (in relative time) before spending, or it can be revoked immediately if a signature with the revocation keys is provided. Its usefulness can be demonstrated with an example:

Take the example where a transaction from Alice to Eric passed through a channel between Alice and Bob. Let's say a couple of days passed and Alice and Bob has exchanged other transactions since. Without second level HTLC Bob could broadcast the old commitment transaction and try to claim the HTLC-output money by providing the pre-image. With second-level HTLC Bob needs to wait a relative time before the money properly becomes his. If the old commit was properly revoked Alice could revoke Bob's attempt at claiming the HTLC-output. Same holds true the other way around if Alice tries to claim an old HTLC output by waiting for the timeout.

Figure 2.9 is the equivalent transaction flow diagram for a channel where the third commit contains a HTLC-output. **To keep the diagram from exploding completely all the previous and following commitment transactions has been excluded.** Also included are all the revocations, so it can be assumed that other commitments were made on this channel after this one.

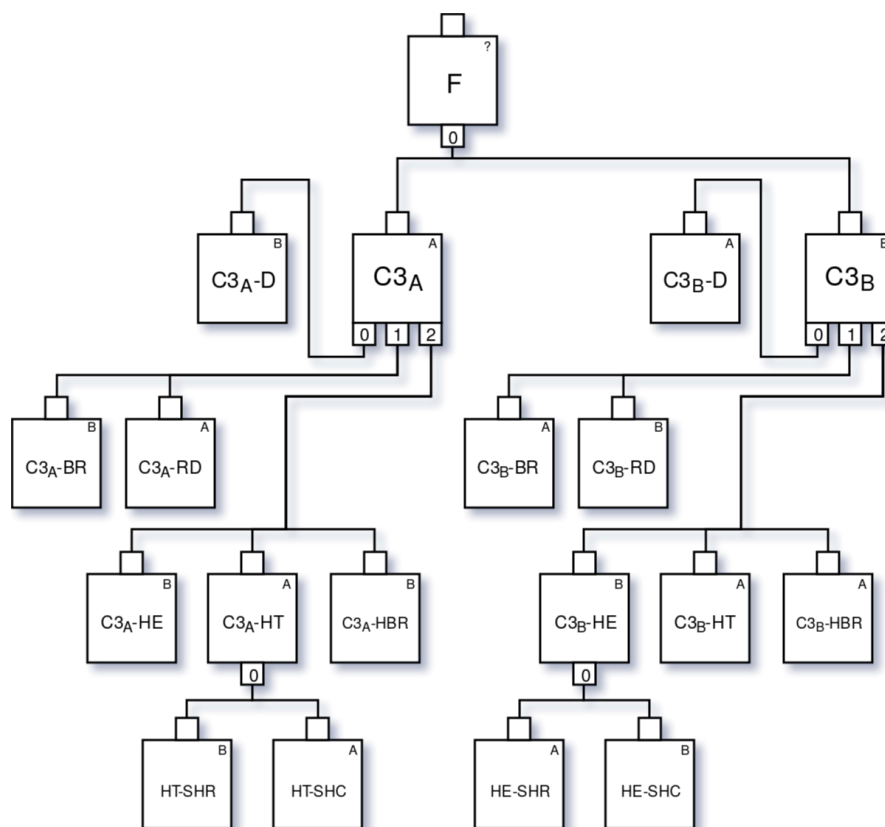

Figure 2.9: The transaction diagram showing the htlc-outputs this time. In the diagram Alice (A) is the sender and Bob (B) is the receiver

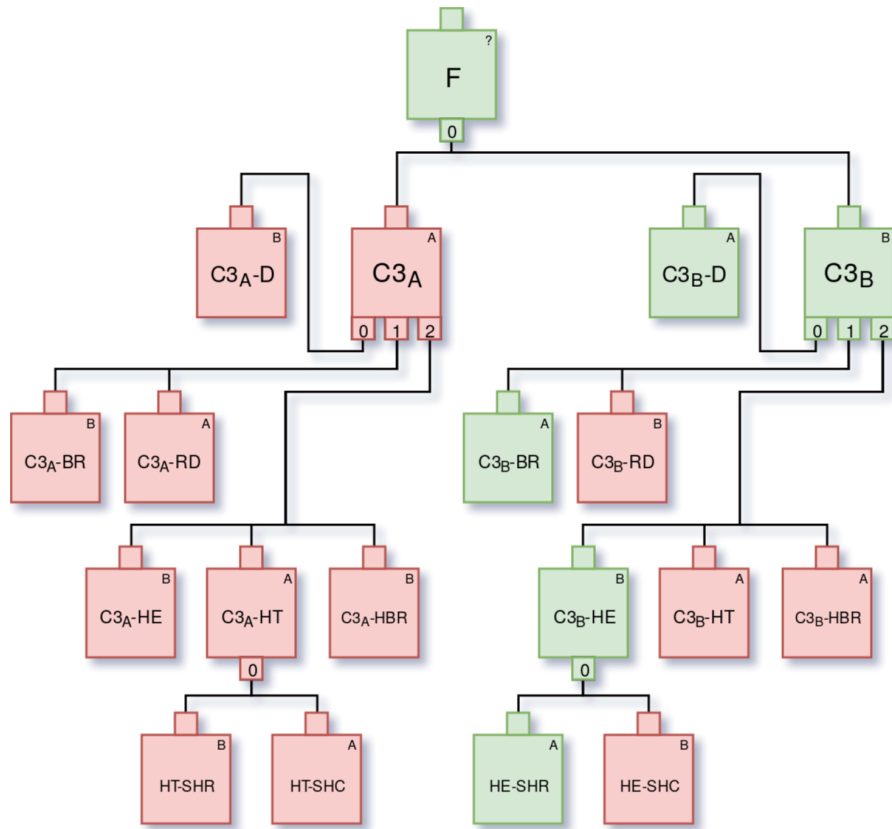

Figure 2.10: Same transaction diagram showing the transactions that are broadcast in case of breach. Red means that the transaction is invalid (cannot be broadcast), green means it was broadcast

Figure 2.10 shows an example of a channel that was closed abruptly and how a party that tries to cheat the other loses all the money they had in the channel. Let's say Alice and Bob has a channel and commit 3 ($C3$, the one in the figure) is an old commit that has been revoked. Bob has the pre-image required to claim the HTLC-output in commit 3 so he decides to close the channel using this commitment in an attempt to gain money that is not his according to the rules.

He broadcasts his third commit ($C3_B$), thus invalidating any other commitment transactions derived from the funding transaction (F). All transactions on Alices side of the commitment tree are thus invalidated. The 0th output of $C3_B$ can only be claimed by Alice, and she does this with $C3_B-D$ (Delivery). The 1st output is the one that normally would go to Bob after a relative timelock had passed (using $C3_B-RD$ (Revocable delivery)), but when this commitment was revoked a new breach remedy was created. Alice can claim the 1st output immediately by broadcasting $C3_B-1BR$ (Breach remedy).

The 2nd output on $C3_B$ is the HTLC-output. This output has also been revoked with $C3_B-HBR$ (HTLC Breach Remedy), so if Alice is quick she can claim this output also. But for the sake of showing the dynamics surrounding second-level HTLC let's say that Bob broadcast $C3_B-HE$ (HTLC Execution) really fast. This transaction pays into a second-level HTLC contract, Bob needs to wait a for a relative timelock to expire before he can claim this output with $HE-SHC$ (Second-level HTLC claim). However when the commit was revoked a breach remedy for this second-level HTLC contract was created also. To claim the HTLC-output Alice needs to broadcast $HE-SHR$ (Second-level HTLC revoke).

This process completes the closing of the channel as there are no more unspent outputs, Bobs attempt at cheating has cost him all the money he had in the channel.

Figure 2.11 shows a different scenario where Alice tries to cheat Bob with an old commit. The exact details of the scenario is left as an exercise for the reader.

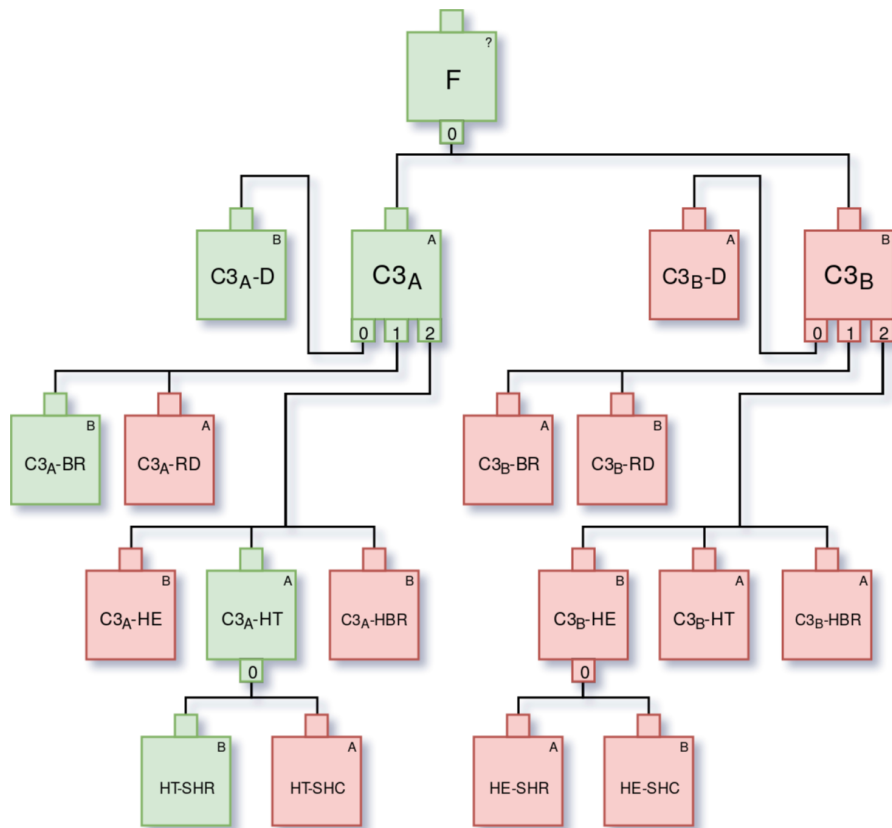

Figure 2.11: Same as figure 2.10, but a different path

Chapter 3

Atomic swaps

3.1 On-chain Atomic swaps

On-chain atomic swaps is a method where two parties can exchange cryptocurrencies between different chains in an atomic way, in this case it means that none of the parties can cheat the other and no matter what state in the exchange-process the swap is either completed or reversed entirely, to the pre-exchange state. The on-chain distinction comes from the fact that this type of atomic swap occurs entirely on the chains (There is no off-chain transaction in the process).

There are several ways atomic swaps can be performed, scripts, signatures and time locks can take several different combinations in transactions and still retain atomicity. The method that will be described in this report will be a P2SH, pay to contract type. This swap is done with the help of time locked contracts constructed with scripts.

3.1.1 The contracts

A swap contract contains certain components. The initial component is the secret x that is generated by the initial contract creator. The secret is not included in the initial contract however, this is what is included:

- Byte string h - Hash of secret x
- Integer T - Contract expiration time as timestamp
- Address B - Redeemer address
- Address A - Refund address

The contract uses branching provided by the operations `OP_IF`, `OP_ELSE` and `OP_ENDIF`. The branch that is taken during execution is decided by whoever is trying to spend the output. One branch pays to the redeemer address, for it to be valid the secret has to be revealed. The other branch pays to the refund address, but it can only be valid if the current time is equal to or greater than the timestamp T .

Counter party contract

The contract described above is the one constructed by and broadcast by whoever wants to initialize the exchange. A very similar contract has to be constructed and broadcast by the counter party, this contract however contains a few changes. The only variable that remains unchanged is h . T has to be a value between the current time and T from the old contract, denoted $T/2$. Redeemer and refund addresses has to be changed so that the redeemer is whoever constructed the initial contract and the refund address is yourself.

3.1.2 The process

Imagine Alice and Bob wants to swap cryptocurrencies. Alice has Bitcoin and wants Litecoin, Bob vice versa. Alice is the initiator in this case. The process would be the following:

1. Alice generates a new secret and then constructs a contract from the variables needed as stated above.
2. She broadcasts a p2sh transaction (to the Bitcoin blockchain) that pays to the constructed contract, called the contract transaction. Alice then sends the contract and the contract transaction txid to Bob.
3. Bob fetches the transaction from the Bitcoin blockchain and validates all the variables, as well as the contract to contract hash etc. . .
4. If all seems to be in order, Bob can construct his own contract using the same secret hash h as Alice did in her contract. This time however the timelock is set to $T/2$. He then broadcasts a transaction paying to the contract on the Litecoin network. Just as Alice did, Bob sends the contract and txid to Alice.
5. Alice validates all the data the same way that Bob did in step 3.
6. If all seems to be in order. Alice could claim the Litecoins from Bobs contract transaction by making a transaction spending the output. The input that validates the output script must contain the secret x to be valid.
7. Meanwhile Bob monitors the Litecoin chain for someone spending his contract transaction. If somebody does it means that they know the secret x . Any information in the blockchain can be extracted, Bob needs to know x to spend Alice's contract transaction. If somebodies spends his contract transaction he can extract x from that and spend the Bitcoin side transaction.

Visualizer

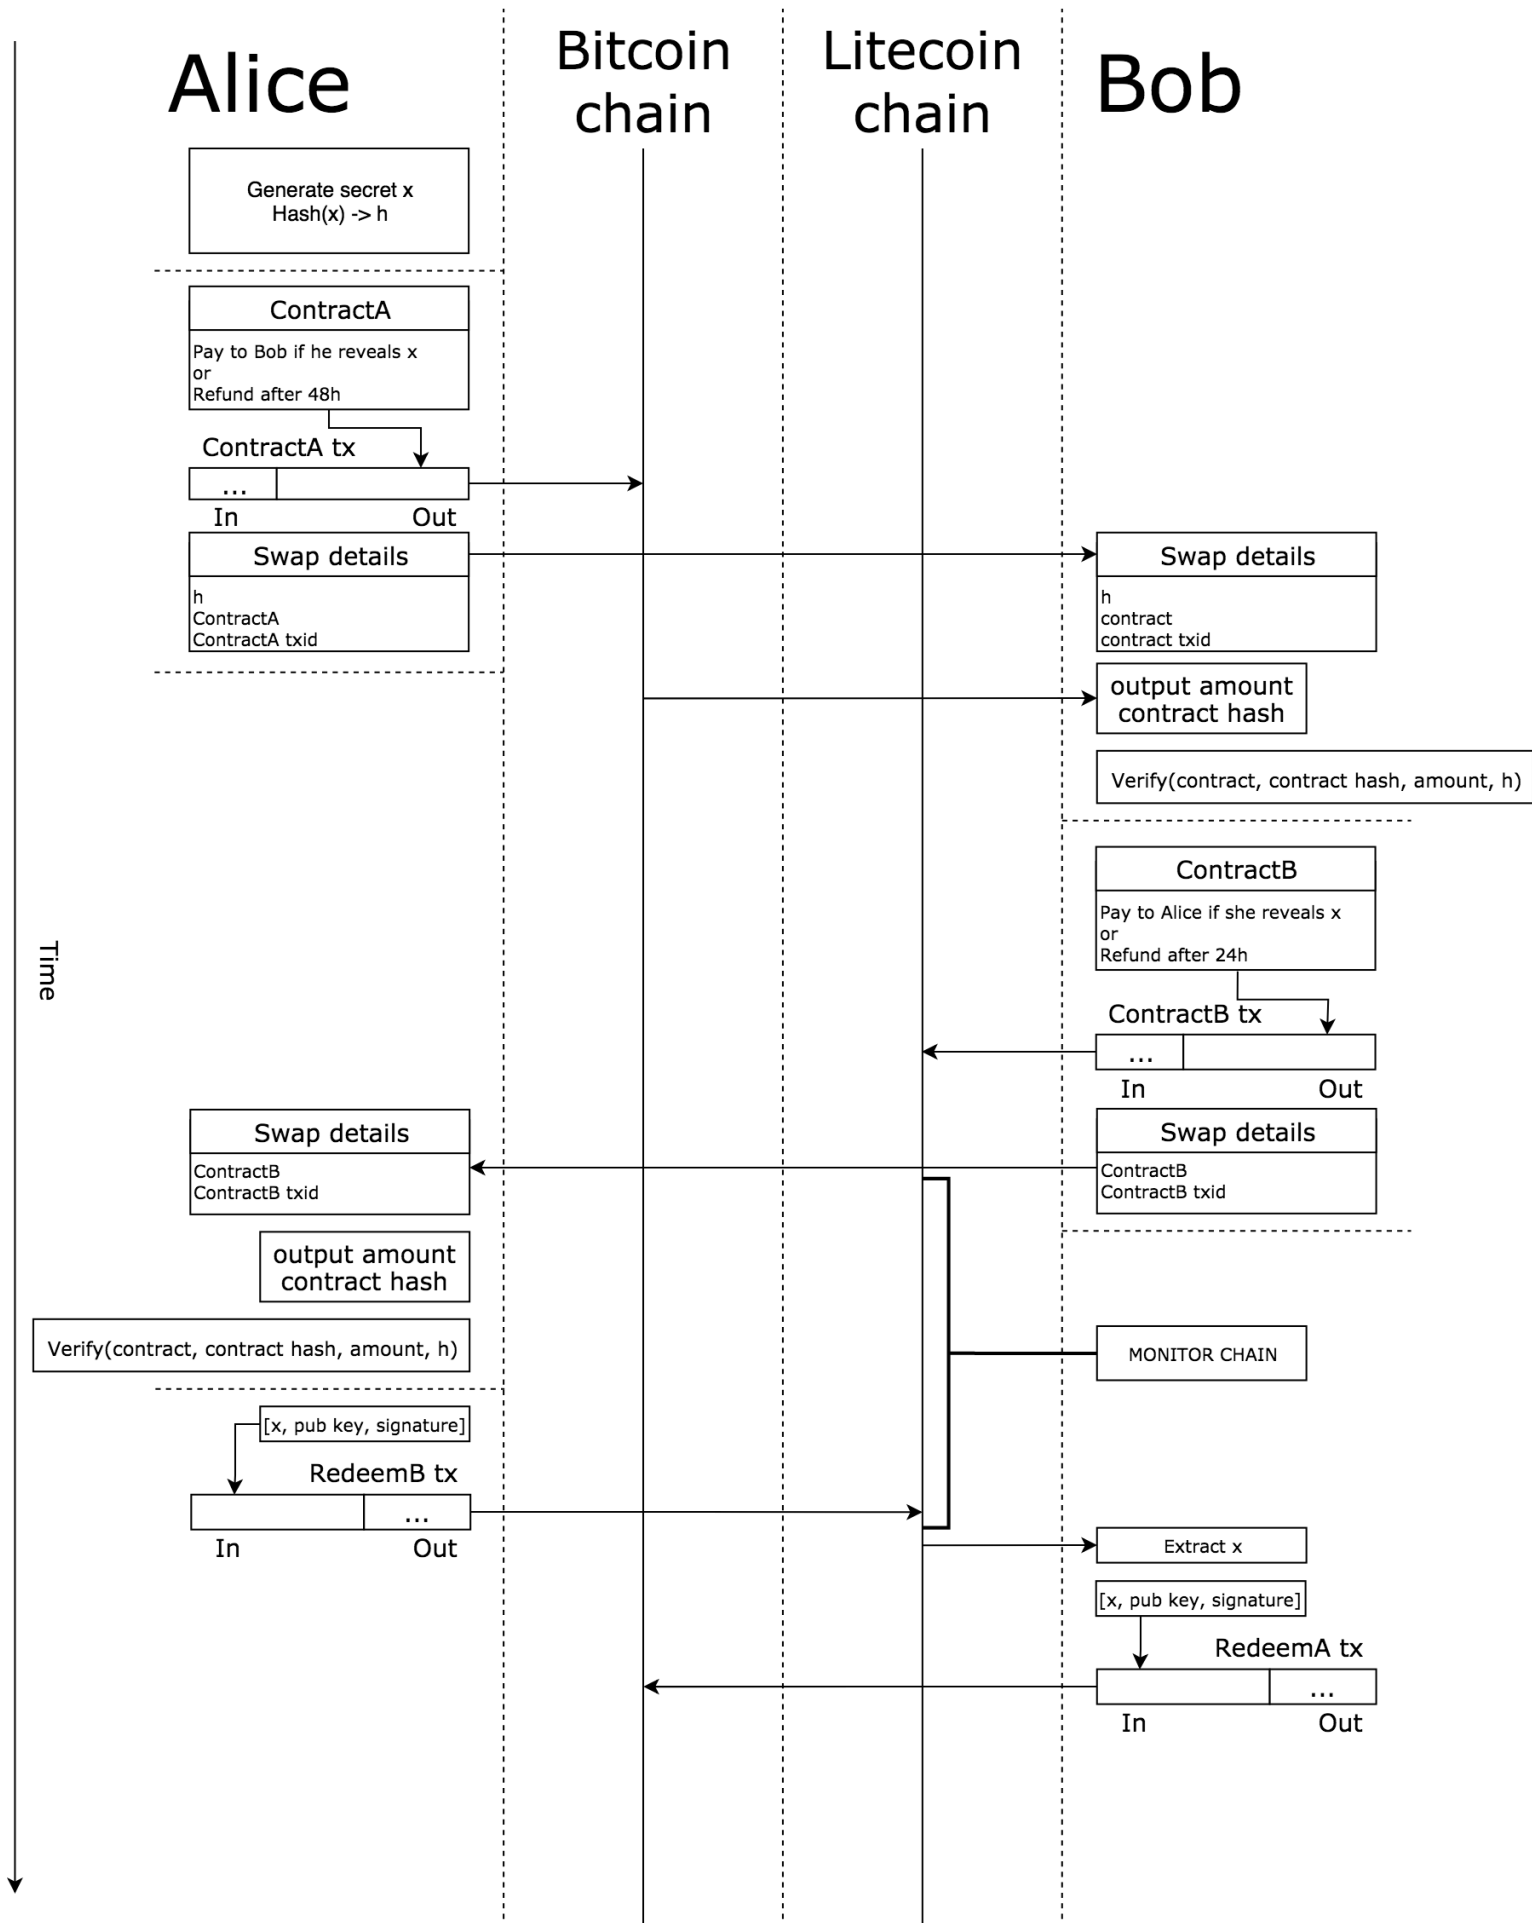

The next page contains a diagram visualizing the process described above. T is set to 48 hour after initialization in the example, thus $T/2$ would be 24 hours.

3.1.3 Atomicity

Easiest way to show the atomicity of the swap is to show what happens if one party stops cooperating during any step in the process. The two trivial cases are before any step in the process, then no transaction has been made and the state did not change at all. If one becomes uncooperative at the end of the process the state change has already been completed and it does not matter what anyone does. The non-trivial cases is when someone becomes uncooperative mid process.

The first case we will look at is if Bob stops responding after step 2. Meaning he never broadcasts his side of the contract. Then Alice simply never reveals x , Bob needs x to claim the Bitcoins. Alice then just waits until timelock T has passed and refunds the transaction. After the refund the state has been reset to the initial state.

The second case is if Alice becomes unresponsive after Bob has broadcast his side of the contract. Bob can not do anything until he knows x or the timelock ($T/2$) of his transaction expires. If Alice does nothing Bob will never know x and thus has to wait to refund his transaction. Presumably Alice does the same after timelock T expires. The state has been reset to the initial one.

3.1.4 How the swap could fail

The atomicity of the swap depends on each party acting rationally and not doing any mistakes that compromises the process. For example if Alice broadcasts her side of the contract and then reveals x to Bob thorough some alternative communication channel then Bob could claim the Bitcoins without doing his part of the deal.

Malformed contracts could also lead to money being stolen. This is why the validation steps are very important. For example Alice could maliciously set her contract to expire earlier than Bobs if Bob is not careful.

Actors in the scenario doing nothing also compromises the swap. If Alice waits until after $T/2$ expires before attempting to claim the Litecoins she is risking out on losing both the currencies. Bob could monitor the transaction pool, seeing what x was, then sneak in his own refund transaction reclaiming his Litecoins (This is possible as the refund branch of the contract now is unlocked). Then also claiming the Bitcoins before T expires.

3.2 Off-chain atomic swaps

Atomic swaps over a payment channel is possible, often refered to as off-chain atomic swap. The mechanisms that makes it work may not be as clear as one that takes place entirely on-chain.

To clear some things up before moving on: **both** parties that are performing the swap needs to have a functioning node on the respective networks of the cryptocurrencies to be exchanged. The channels do **not** need to be directly connected to each other instead they can take any route through both networks, given that the route allows the exchanged amount of course.

If we say that Alice (A) and Bob (B) want to do an off-chain atomic swap, Alice has bitcoins and wants litecoins, Bob has litecoins and wants bitcoins. Let us also say that Alice is the one that initiates the swap (meaning that in this case she sends the initial transaction). An off-chain atomic swap can be thought of as a transaction that propagates through both the networks. Alice sends a transaction to Bob on the bitcoin network, Bob re-sends a transaction with the same pre-image hash on the litecoin network to Alice. The timelocks are set so that the time continually decreases (like it would on a regular network transaction), even as it transitions into the litecoin network. Let us say that there are m jumps between Alice and Bob on the bitcoin network and n jumps between them on the litecoin network, and that each step needs at least 24 hours more to claim for each step.

The timelock on the initial channel jump (the one Alice sends initially) would be:

$$(m + n + 1) * 24h$$

When the transaction reaches Bob the timelock should be:

$$(n + 1) * 24h$$

This is where the swap differs from a normal transaction. In a regular transaction Bob would be the holder of the pre-image, and thus the pre-image could properly propagate backwards in the transaction chain from here. But in this case he does not know the pre-image and thus is forced to continue the chain on the litecoin chain if he ever wants to claim his bitcoins. As mentioned he sends the agreed upon litecoins to Alice via the litecoin network, still using the same pre-image hash used by Alice. He also continues with the same decreasing timelock (thus the next transaction will have a timelock of $((n + 1) - 1) * 24h$)

When the transaction on the litecoin network at last arrives to Alice the timelock should be set to:

$$(1) * 24h$$

When the litecoin transaction reaches Alice the circle is closed and Alice can safely reveal the pre-image. Every one in the transaction chain gets their rightful money. When the pre-image reaches Bob he has to propagate it backwards on the bitcoin network until it reaches Alice again. Just as with regular multi-hop transactions each channel is expected to settle without closing and spending the HTLC-output unless necessary due to uncooperative nodes etc...

As long as the same pre-image is used and the timelocks decrease monotonically across the networks this should be a safe swap. If Bob tries to cheat Alice by not sending the agreed upon amount of litecoins Alice simply has to never reveal the pre-image anyone in the chain. Then all multi-hop transactions on both chains will have to be reset after the timelocks have expired.

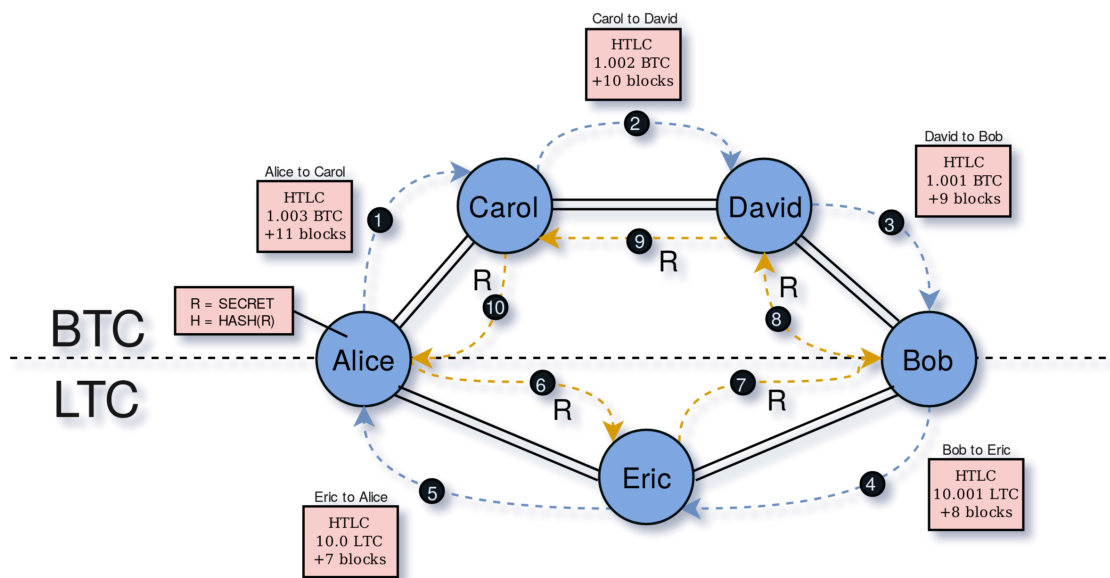

Figure 3.1: Route taken by the multi-hop transactions on both networks. Note that Alice and Bob has a node in both the BTC and LTC network.

Figure 3.1 shows a rough diagram of the process. Alice and Bob has an active node in both the networks, no such assumption is needed for the other participants on either side. As mentioned the transaction could pass as many intermittent nodes as needed on either network, to keep the diagram small only two additional jumps are made on the Bitcoin side, and only one extra jump on the litecoin network.

So to summarize the process:

Alice and Bob agrees on doing a swap, they agree to exchange 1 bitcoin for 10 litecoins. Alice creates a new secret R and a new hash $H = \text{HASH}(R)$. Sends a off-chain transaction to Bob on the bitcoin network that gives him 1 bitcoin if he can provide the pre-image to H (R) (Steps 1 - 3 in the diagram). Bob sends a multi-hop transaction to Alice on the litecoin network, that gives Alice 10 litecoins if she can provide the pre-image to H (Steps 4 - 5 in the diagram). It is very important that the decreasing timelock that was used on the bitcoin side continues on the litecoin side. Otherwise the safety of the swap is not guaranteed.

When Alice receives the litecoin transaction, she can safely reveal R to Eric, Eric will do

the same to Bob. The R will travel backwards in the transaction chain just like with a regular lightning network transaction, but this time when the pre-image reaches Bob he will keep transmitting it backwards through the chain on the bitcoin network. (Steps 6 - 10 in the diagram).

3.2.1 Safety

The way safety is assured in off-chain atomic swaps is the same mechanisms that makes lightning network it self safe, which in turn is largely based on the mechanisms of the on-chain atomic swap. Let us take a look at a couple of scenarios where malicious actors try to claim money that is not theirs. Using the general scenario shown in figure 3.1.

Bob does not send his litecoins to Alice after receiving bitcoins

This would be after step 3 in the diagram. At first it may seem that Bob will get his bitcoins after all, but Alice simply has to never reveal the pre-image R. The HTLC contract states that everyone along the chain can only claim their money if they can reveal the pre-image to the hash H. If Alice never reveals it, Carol, David and Bob will not be able to claim the money. In the optimal case no channel will have to close in this scenario, after the timelock has expired nobody on the chain has any reason not to amend the previous commit with HTLC with a new commit with the transactions reversed. In the worst case, meaning that everybody refuses to cooperate, all the channels on the BTC side of the diagram has to be closed. The transaction reversal will be reflected on in the money that is now claimable on-chain.

In both the worst and best case no monetary loss has occurred for any of the participants in the network.

Alice tries to claim the litecoins without revealing the pre-image to Eric

In this case she will be able to claim her litecoins. But claiming them on-chain will also reveal the secret R publicly on the blockchain. Even if Alice waited until just before the timelock expired to claim her litecoins, in this case 6 blocks, there is still time over for Eric to claim his litecoins on the Bob channel as that channel has a larger timelock. In the best case scenario only the channel between Alice and Eric is closed, while the rest settles normally (in this case in favor of the transaction). In the worst case all channels will have to be closed. Even so nobody will lose out on their share of the money as the timelock is ever increasing when going backwards in the payment chain, and for each step on the way the pre-image will be revealed on the blockchain just as it did between Alice and Eric.

Somebody along the path stops cooperating

Let us say Eric did not forward the transaction to Alice. This is just a variation of the first scenario. If Alice sees that something is wrong she will simply not reveal the pre-image to anyone and all channels will have to revert to previous state or be closed.

Chapter 4

Implementation

To implement the described types of atomic swaps, Go (golang) was used together with the standard libraries plus external libraries from the **btcsuite**: **btcsuite/btcd** and **btcsuite/btcutil**, as well as **lightningnetwork/lnd**, all of which can be found on github.com. The implementations are simplified, just like with this report the focus was on making it easy to understand for newcomers.

To interact with the different blockchains two different full-nodes was setup. **Bitcoin Core 17.1** for bitcoin and **Litecoin Core v0.16.3.0-82cacfe8**. Both running on their respective *testnet*. Both nodes have a RPC interface to interact with the blockchain and the rest of the network.

4.1 On-chain atomic swaps

The implementation creates two simulated peers, called Alice and Bob. Each participant is represented by the wallet name used in the node programs. The entire process is divided up into 4 smaller programs. The first program generates the contract and contract transactions and prints it on **stdout** in hex format. The second program takes the contract as input and prints the contract transaction for the litecoin side of the swap.

The last two programs are used to redeem the contract transactions. Logically you should run the litecoin side program first and claim the litecoins as Alice knows the secret. The third program takes the secret as input and prints the transaction that can claim the litecoins. The fourth program takes the secret and creates the claim transaction for the bitcoins.

Overall the on-chain swap implementation is sloppy and not super easy to follow. In the off-chain swap implementation everything was put into one program, with clearly defined datatypes and it relies a lot less on the nodes for support with private keys and public keys.

The swapping programs does not themselves send any transactions to the blockchain, that has to be done by the user manually.

4.1.1 Details on script

The script used to create the contract is based on the suggested atomic-swap contract that can be found in **btcd**. More specifically there is a function that comes with the **btcd** library that can extract data from swap contracts, so the contract designed in this solution was designed so that it is compatible with this function.

```
OP_IF
  OP_SIZE
  <Byte length of secret>
  OP_EQUALVERIFY

  OP_SHA256
  <Hash of secret>
  OP_EQUALVERIFY

  OP_DUP
  OP_HASH160
  <Receiver address>
OP_ELSE
  <Locktime>
  OP_CHECKLOCKTIMEVERIFY
  OP_DROP

  OP_DUP
  OP_HAASH160
  <Refund address>
OP_ENDIF

OP_EQUALVERIFY
OP_CHECKSIG
```

A contract following this format can be used by the contract details extractor function to extract all the data pushes, like locktime and hash of secret.

4.2 Off-chain atomic swap

The implementation of the off-chain swap was considerably more robust and better coded. The solution creates two fake people Alice and Bob, who via two payment channels performs an atomic swap from bitcoin to litecoin (In Alices perspective). Both the peers and channel has proper data structures and related functions. The process starts with opening of both channels. The channel opening consists of generating the funding transaction and the first commitment transaction. Just as before they are printed to `stdout` in hex encoding, and also like before all transactions has to be broadcast manually. In this case however you dont really need to transmit any transactions until the channel closes, The commitments coming after the first ones assume that the funding transaction has been broadcast, but they never check for it. So you could run the simulation without actually performing any transactions on-chain.

The payment channels in this implementation supports regular transactions between the peers. The implementation is an exact clone of how it works in the lightning network minus all the protocol and multi-hoping. Some liberties are taken with how data is stored and the order of how things are done. For example all data related to things like private keys are stored on the same computer. In a real life scenario this would be very unsafe, but making the experiment using two computers would be needlessly complicated, so it was skipped. An example of things being out of order is the revocation of commitment transactions, which in this solution is done at the same time as the commitment itself. This is also completely unsafe in any real life scenario, all money would be stolen if any commitment transaction was broadcast.

The implementation has a special function where the real swapping magic takes place. It

takes in two channels, the ones we created earlier, and performs the atomic swap between them. The regular channel payment function that is contained in the payment channel object takes in a payment descriptor that takes in information about the transaction, the descriptor holds data like amount, sender and receiver, but also the pre-image hash that should be used plus the timelock.

The swap function performs the swap by first sending bitcoins from Alice to Bob, then litecoin from Bob to Alice using the same pre-image hash and with a halved time in the future in the timelock. It then simulates pre-image reveal and settles both channels with the updated value.

All outcomes of the transaction is tested. That means all possible scenarios and outcomes from the htlc contract on both channels. The test was by trying all scenarios by broadcasting the commitment transactions on the testnet chains along with all transactions that settles the htlc and other outputs.

4.2.1 Implementation specifics

Both the channels used a variation of the implementation that can be found in lnd. With a few modifications to allow the custom channel setup. As mentioned none of the BOLT protocol and databases were used.

All the scripts for the different contracts were as described in the BOLT specification. Because of an initial misunderstanding there is a second-level htlc bot on the htlc-success path and the timeout-path on both sides of the commitment transaction. This is not correct, but it does not affect the security or the swaps in any way so it was left in.

Chapter 5

Results & Proposal

In this section I will talk about the results I got when performing the types of atomic swaps detailed in previous chapters, and from these and my experience I will make a few proposals on how atomic swaps could be standardized into clearly defined protocols and procedures.

5.1 On-chain atomic swaps

In my implementation I created a scenario where two parties swapped bitcoins for litecoins, on their respective testnets. The swap was tested for all possible outcomes and possible actions by the actors. And in all cases the swap acted in an atomic way, meaning that either the exchange took place fully or the state was eventually reset to the original. As expected an on-chain atomic swap takes some time to perform. With the values for the timelocks used in my experiment the swap could take up to 48 hours to complete in a worst case scenario. The timelock values could be decreased at the cost of increased risk of failure.

Under the assumption that the contract transactions, and claim transactions are included in their respective next block an atomic swap can take at best ~ 25 minutes (Using the average block times for the respective chains, 10 minutes and 2.5 minutes). Both participants have to stay attentive during the whole span (25m - 2880m), in computing terms this is a very long time.

Under the assumption that Alice (A) is the one who initiated the swap, and Bob (B) is the counter party. A holds the power to control the earliest time that the swap could be completed, before A reveals the pre-image in the blockchain B can do nothing but wait. It could be argued that this is not a swap at all but instead a type of option. If A never reveals the pre-image the swap will be revert back to the pre-swap state. Alice and Bob could agree on a swap at a certain rate, then A could wait it out to see if she could get a better deal (as exchange rates are constantly changing) or decide not to go through with it if agreed upon exchange rate is worse than the current one. A cost for the privilege of this decision could be added to the initial contract transaction as an extra output giving a small sum of money to Bob.

The swap vs option discussion is interesting, I will however focus more on the technical details in this report, and will leave this topic for future discussion at another time.

The two sub sections below holds proposals on how wallet and node software could be changed/upgraded to best support atomic swaps in the future. Both runs on the premise that the manual input and interaction from the participants should be kept at minimum possible level and that most of the process should be automated by software and hardware.

5.1.1 Proposed solution

The easiest way is to modify wallet software so that it can facilitate atomic swaps, not the matching between the swapees, that could be handled through other channels. The largest problem is not the creation of the swap itself. But rather the fact that the blockchain has to be monitored and the pre-image extracted. Most wallets do not monitor two different blockchains, but rather only the one it was made to hold currency from.

There exist wallets that can handle transactions on multiple blockchains. Something they all have in common is the lack of self-owned nodes. When the node your wallet is interacting with is owned by someone other than yourself there is risk. The owner of the node and the other party (they could even be the same person) in the swap could be cooperating to deceive you.

The only truly risk-free way to handle a cross-chain swap is to run your own nodes on the crypto-currency chains which you wish to swap. This is a pretty large hassle if you only want to perform a single swap, it is a trade off between invested time and risk.

For the completely risk-free trustless solution I propose a wallet that is capable of managing cryptocurrencies of different kinds, interactions with blockchains happens via RPC connections to the full-node. Under the assumption that both parties are using this hypothetical wallet making an atomic swap is fairly simple. Either the wallets could communicate and exchange data like addresses and contracts automatically, or that data could be exchanged manually via some other type of channel.

The process will still be as described in previous chapters, in this case the wallet will manage all the time-critical tasks and monitoring that is difficult or tedious for a human to do.

5.1.2 Third-party alternative solution

If the amount exchanged is small enough, taking a slightly higher risk might be deemed acceptable by the participants. A third-party service could be constructed so that it can handle the time-critical parts of the swap. The contract transactions will be broadcast normally by the participants. If using segregated witness, both the claiming and timelock-refund transactions could be pre-constructed and signed by the participants, then sent to this hypothetical service.

The service could take a small fee for the job, but for now let us imagine it is free. The service monitors all blockchains that it supports swaps for. When it receives a contract and the related spending transactions it can monitor the blockchains for the contract transactions. When it sees one that it has the spending transaction for it can extract the pre-image and insert it into the input script of the claim transaction. It can do this for both sides of the swap. If the initiator never reveals the pre-image the service can broadcast the refund transactions to revert the state back to normal (only after the timelock has expired of course).

Inserting the pre-image into an already signed transaction is only possible thanks to segregated witness as otherwise the pre-image would alter the transaction id and the signature would be invalid.

This is as mentioned earlier not entirely risk free, a rogue service could choose to not broadcast a claim transaction in time and thus letting one participant claim both sides of the swap. If the service came with a small fee the service would be encouraged to not cheat the users and losing out on future fee revenue. Using a third-party is very convenient but comes at a price, in the form of risk. I would only recommend using such a service if you rarely do atomic swaps or you are swapping tiny amounts.

5.2 Off-chain atomic swaps

How off-chain atomic swaps are performed are a bit harder to understand and required a lot more work, and yet in my opinion they hold more potential for the future. The limitation that comes with having more than one node running still exists, but the cost that comes with broadcasting transactions on-chain is almost completely removed.

In my experiments I did open a proper channel and performed an atomic swap. I did not however do it over the real lightning network, mostly due to time constraints and it not being necessary to prove that it worked. Doing it over a proper lightning network would require additional tweaks to the protocol and would take significantly more time. In my simulation I did not perform any multi-hop transactions over nodes not involved in the swap, the fact that it still would work over multiple hops is evident in the mechanisms of the swap.

5.2.1 Solution proposal

Doing the swaps on a payment channel that is not part of the lightning network like I did in my experiments works fine, the problem is that the two participants have to have channels open that are dedicated to doing swaps between them and nobody else. This is fine for a couple of implementations, like for exchanges or banks etc. It would not be very fitting as a general solution however.

To make off-chain atomic swaps possible in a more general setting, like the main lightning network, some changes have to be made to the protocol.

BOLT and c-lightning

All nodes participating in the lightning network follow a set of rules and protocols that are defined in the BOLT specification.^[8] My first thought were to simply propose a few changes to the protocol to allow swaps, but there is a simpler solution that makes the implementation even more versatile.

The writers of the BOLT specification has purposely left openings in the flag and protocol structure to allow for easy extensions.^[8] This is what is known as "it's ok to be odd rule", what that means is that any message with an even number should be supported by all nodes. Messages with odd numbers are interpreted as optional. If the node receives a message with an odd number that it does not recognize it will simply be ignored (unknown even messages should result in closing of the connection as the nodes most likely have different version numbers).

There are also flags in the BOLT specification that nodes tell each other about upon connection. A flag is a bit set to 1 or 0 in a bytestring, and they represent a supported feature. As before these flags follow the "it's ok to be odd rule". Thus flags in even positions are features that must be supported, and flags in odd positions represent optional features that this node support.

BOLT is designed to support more than bitcoin with the help of the `chain_hash` variable. The chain hash is the unique identifier for the genesis block on whatever blockchain you refer to in a specific protocol message. If a node receives a chain hash it does not recognize or does not support it will ignore that message.^[8]

Another interesting aspect is the new plugin system for the node implementation: **c-lightning**. This plugin system allows for functionality additions that does not need to be part of the main implementation code.

A non-disruptive solution

My proposed solution involves making a plugin for c-lightning (and any other node as soon as they add plugin support). The plugin add an additional feature flag in any open odd position. The flag represents support and potential willingness to perform swaps across chains.

One of the aspects i find most interesting with the off-chain atomic swaps is the fact that the other nodes (in the case of a multi-hop path) does not need to know that the transaction they are propagating is part of a swap. In other words they do not need to have the plugin themselves to be part of the atomic swap. Only the two end nodes on each side of the swap, meaning the two participants in the swap needs to run special plugin software.

The plugin's normal operation outside the feature flag addition will be handling of forwarding new htlc outputs. When it receives a pre-image that is not related to any atomic-swap it will be handled like any normal htlc request would. When it sees a htlc related to a known atomic swap however it will handle it as a special case.

For now let us assume that the swapping parties reached their agreement through a separate channel. The details they need to agree upon are how much to be exchanged and at what rate, and also they need to make sure that there is a viable path between them on sides of the network, both to know if the swap is possible at all, and to know what timelock to start on. Let us also assume that Alice is the one who initiates the exchange.

In a normal transaction Bob would be the one who generates the pre-image used in the transaction chain started by Alice. In the case of a swap this would not work however, as she will ultimately be the nreceiver on the other end when she receives the other type of crypto-currency. Thus before the exchange begins Alice will generate the pre-image and sends the hash of it to Bob.

When these variables are agreed upon Alice can send the bitcoins to Bob on the bitcoin side of the network. When the transaction reaches Bob is where the plugin kicks in. It keeps track of agrred upon swaps and what pre-image hash that they will use. When the new transaction comes in with the hash they agreed upon earlier the plugin will act differently than normal operations. It will recognize the hash and match it to the details of the swap. It can then send the promised money on the litecoin side of the network to Alice, using the same pre-image hash and continuing on the same timelock.

As can be seen the plugin is quite simple but still allows for some complex behaviour, and it is very non-disruptive. It requires no extra software or special nodes running on their own network.

5.2.2 Alternative third-party solutions

Even in off-chain atomic swaps there is a possibility for a third-party solution, though in this case it is not entirely atomic, the risk in the exchanged can be minimized as much as the participants want. One thing we are used to in our regular financial system is that most transactions and exchanges are made in lump sums, meaning the whole value of something is transacted in one go. Payment channels and lightning network introduces a new method: streaming. In the lightning network there is nothing stopping you from splitting up a transaction into smaller parts. This could be seen as packets in a stream, each packet shifting the value balance between two parties.

This streaming could change how we think of transactions. As an example imagine a tv-series streaming service. Instead of paying per month with money streaming you could be paying per watched hour, or even minute or second. You could imagine a parking space

that automatically withdraws money per minute that you are parked in that spot. The future of these money streams is a discussion for another day though and for now I will focus on how they could be utilized for swaps.

A service could be setup so that anyone wanting to exchange a currency for another (for example bitcoin to litecoin) could stream bitcoin into the service and have a stream of litecoin coming back. The service itself would not be the one providing the litecoins, instead someone on the other end would have the same stream setup but with the currencies swapped. It could be said that what the service really does is connecting streams, like pipes. The users does not even need to know who they are connected to, they only need to worry about getting the currency they requested at the rate they want.

So what is stopping the service from just closing all channels and running away with the money? This is where the streams come in handy. Each participant only sends a really tiny amount at a time, and does not send the next package until they have received the right amount on the channel of the other currency. The service could at most steal the amount used in one "stream" package. The user could adjust the amount sent in each package to whatever value they are willing to risk. With a functioning fee system, the service would be encouraged to not cheat their users and being seen as not trustworthy, the fee could be sent with each package, and be proportional to the amount.

Some logistical problems arises when users are using different amounts in their packages. If the amounts does not even out the exchange can dead-lock as I have described it so far. Let us say one user uses package size of x and another user is trying to exchange for that currency but is using size $x1.5$. Then the latter user will not send the next package as they have not received the full promised amount, and the former user will stop sending after only receiving $x0.5$ for their second package. This could be solved by the service communicating with the users about the situation and they simply have to adjust accordingly. It could also be solved by the service setting a set package size for each currency that all users have to adhere to.

So to summarize; a service could be built so that it connects streams of swaps like pipes. All said and done this is not an atomic swap, as it is not fully atomic. It is however a method of swapping where the risk could be minimized as much as the user wants. It could also end up being more practical than organizing all swaps in a completely distributed manner.

Chapter 6

Discussion & Future research

Overall I am happy with the work. The project started out with goals that were different than what it ended up being. What I am most unhappy about is that I realized so late into the project a much better goal, leading to a lot of time being wasted on experiments that were not particularly useful.

If I could do the project over again my focus would have been more on actually developing the swapping plugin described in chapter 5. I feel personally that this would have been much more fulfilling, and it would have been a better demonstration of my actual proposal. As it is not the experiments and the proposal feels a bit disconnected, what I mean is that I could have reached the conclusion without performing most of the experiments. Even though my implementation was not entirely necessary I am still happy I did them, as there is very little information about atomic swaps especially the off-chain form. It was nice to get first hand experience with actual development using bitcoin tools and libraries, and experience with programmed contracts.

I plan to at least give it a try to implement the plugin, but it will be during the coming summer and outside the scope of this thesis.

6.1 Future research

There are plenty of topics of interest around swaps that could be explored further:

- **eltoo and transaction binding**

A potential update to bitcoin will add an additional sighash called `SIGHASH_NOINPUT`. This new sighash removes the need to sign the input field of the transaction. This makes opening of channels easier as now both participants can safely fund the channel. But more importantly it allows for something called transaction binding, this is a concept where the txid that reference where which transaction output is being spent can be changed after signing, thus "changing the binding"

eltoo is the name of the proposed change in payment channel protocol, this change requires the new sighash to work. I will not go into detail here but the gist of the update is a change so that the commitment transactions that make up the channel become symmetrical and it removes the breach remedy entirely, because there is no way to broadcast and spend an old commitment transaction. As far as I know there is little change to how htlcs operate so my master-thesis should still be compatible, but it is worth looking into.

Perhaps there is a yet undiscovered method of doing swaps using the new utility

provided by `SIGHASH_NOINPUT`. This is also worth looking into

- **Economics of atomic swaps**

Another potential for future research is the viability of using atomic swaps in actual financial settings. Analyzing things like time and cost could be very valuable, and could decide if atomic swaps actually have a future outside of being an interesting gimmick.

- **Off-chain swaps as routing method**

This is a pretty wild idea and I have no idea if it is viable in anyway, but as shown by the off-chain atomic swap a multi-hop transaction does not have to do all hops on the same chain, in fact the atomic swap described in the chapters above only switches chain once along the path but that is by no way a requirement, the transaction could switch chain any arbitrary number of times along the path. But at great cost of organizing and etc... Perhaps this method could be used to make cheaper multi-hop transactions, by making it travel across a chain with lower fees part of the way to it's destination. This is probably way to complicated to organize and gives very little benefit, but might be worth looking into anyways.

The fact that the only requirement for a multi-hop transaction staying safe and consistent is keeping the same pre-image hash and using a strictly decreasing timelock all the way to the destination opens up potential for use and abuse by routing nodes. If you imagine someone hosting several routing nodes in the lightning network. If they know the destination node of a mutli-hop transaction passing through one of their routing nodes, and they have a routing node along the path, they could "teleport" the transaction to the latter node and claim all the fees of the nodes that the transaction should normally have passed through. This might not work with the onion routing implemented by the lightning network protocol, but still worth taking a look at.
